Canids demonstrate wide geographical distribution and are found naturally on every continent, with the exception of Antarctica. Their distribution across a range of diverse habitats results in a wide diversity of dietary intake, with dietary preferences ranging from general carnivore, to omnivore, to opportunist scavenger. Some species demonstrate a more specialist dietary intake represented by insectivores such as the bat-eared fox (*Otocyon megalotis*), although even such apparently specialist feeders will also demonstrate a more general, opportunistic intake based on seasonal availability (Klare et al. 2011). Canine food acquisition strategies range from scavenging and opportunistic foraging intake of animal and plant matter to either group/pack or solitary hunting. Feral dogs have also been observed to hunt medium-sized prey such as deer in packs, with reports also recording humans being hunted (Avis 1999). Consequently, there is a wide diversity within the Caninae in terms of both geographical distribution and dietary intake. For the purposes of this entry, general consideration will be given to the canine diet and notable species-specific

characteristics related to dietary choice, processing, intake, and nutritional requirements.

## Canine Dietary Ecology

Canids demonstrate a diverse range in body size and, as a result, are observed to have a wide diversity in food intake, with both physiology and ecology impacting on dietary availability and choices. Canid body weight typically ranges from about 2 kg to about 80 kg, with some species being much larger. Ingested prey species can range from small insects to large herbivore prey that can be hunted and subdued, either on a group or solitary hunting basis. Indeed, some canids such as the gray wolf (*Canis lupus*) are capable of cooperative hunting as an integral part of their dietary strategy and intake (Mech and Boitani 2003). This permits the acquisition of prey much larger than could be successfully hunted by an individual and is typically via sustained pursuit predation as opposed to the grappling and subduing of prey (Andersson 2005).

While canids are often viewed as carnivores and typically demonstrate the fundamental dentition and a digestive anatomy consistent with a carnivorous diet, many extant canids are not hypercarnivorous, with approximately 70% of their dietary intake coming from animal-derived protein sources and the other 30% coming from plants, seeds, fruits, and other materials. This move toward a more hypocarnivorous and omnivorous dietary strategy is consistent with the typical small to medium body size of many canids. Such dietary flexibility is also a survival advantage in changing environmental circumstances and in part likely accounts for the wide geographical distribution of canids. Many smaller species will undertake solitary hunting/scavenging behaviors and ingest to gut capacity, whereas larger species will have reduced frequency of predation, mitigated by both digestive system capacity and prey size (De Cuyper et al. 2019).

Feeding ecology is also critical in considering the evolutionary success of canids. The ability to survive on a mixed diet permits adaption to altered circumstances and food availability.

Consequently, dietary flexibility is, in part, one reason for the general biological success of the Caninae. Indeed, canid evolution suggests that the larger, hypercarnivorous species such as the dire wolf (*Canis dirus*) that depended predominantly on large, herbivorous species for their dietary intake were negatively affected when prey density started to decrease, with the dire wolf population commencing a decline approximately 20,000 years ago and full extinction occurring about 10,000 years ago (Dundas 1999). The dire wolf is a clear example of a species with a dietary specialization that was incompatible with altered environmental circumstances, and they were effectively outcompeted by the slightly smaller but more dietarily adaptable species such as the gray wolf (Leonard et al. 2007).

## The Canine Digestive System

The typical digestive system of canids resembles that observed in members of Carnivora and demonstrates specific adaptations to support food acquisition (via predation and scavenging), ingestion, and digestive processing. The canine gastrointestinal system is viewed as simple, monogastric, and capable of digesting an omnivorous diet, although often with a high proportion of animal-derived tissue. Consequently, similarities are observed across the Caninae subfamily, with occasional species-specific adaptations, based on specific ecological or dietary niches. The domestic dog has been extensively studied from a digestive anatomy and physiology perspective, and while there are subtle species-specific differences across the Caninae, the canine digestive system is fundamentally similar in structure and function.

### Dentition

In common with their membership of the Carnivora, canids demonstrate the presence of enlarged canines and a carnassial apparatus. These are dental adaptations for acquiring, cutting, shearing, and processing meat that are observed in both extant and extinct carnivorous species (De Muizon and Lange-Badre 2007). The

dental formula of canids is 3142/3143 and includes molars that are unmodified, in contrast to other members of the Carnivora (such as felids) that typically have a reduced dental formula and highly modified molars, congruent with a hypercarnivorous dietary strategy. Notably, the domestic dog has 42 teeth in comparison to the domestic cat, which only has 30 teeth. This dental formula is a useful classification tool and is consistent across canids, apart from the bat-eared fox (*O. megalotis*), dhole (*Cuon alpinus*), and bush dog (*Speothos venaticus*; Wallis 2019).

The carnassial apparatus comprises the fourth upper premolar and the first lower molar and is retained throughout the Caninae. However, in contrast with species that demonstrate an obligate or hypercarnivorous dietary strategy, canid post-carnassial teeth often demonstrate increased palatine surfaces suggestive of a more omnivorous dietary intake and the need for an enhanced grinding surface area, to cope with dietary components of variable shape, size, and density.

Notably, the canid jaw structure only permits vertical movements, supporting the dentition in a strong cutting and shearing action, but severely limits the ability for lateral chewing (Kim et al. 2018). Consequently, prolonged chewing and mechanical processing of ingested foodstuff prior to swallowing are limited, and typical mealtimes are short and characterized by rapid ingestion of available foodstuffs. Bite force is generated by both dentition and jaw structure, with the carnassial apparatus demonstrating a clear secodont or scissor-like action. Bite force generated is closely related to skull size, shape, and overall bodyweight (Kim et al. 2018).

### Digestive Anatomy and Physiology

Beyond dentition, the structure of the typical canid digestive system is short and simple, from point of ingestion to elimination. As a result, gastric transit times are short and there is no prolonged digesta retention time. Indeed, specific anatomical and physiological adaptations for the digestion of plant material, such as extensive microbial fermentation and an extended retention time, are not observed in canids, in contrast to the herbivorous ruminants and hindgut fermenters,

and are suggestive of a diet with high digestibility. However, canid digestion does incorporate various aspects of mechanical, chemical, and some limited microbial digestion processes (Maskell and Johnson 1993), a consequence of a variable and omnivorous intake.

Digestion begins in the mouth with the ingestion of acquired food and some limited mechanical processing due to the limited chewing ability of canids. Saliva is secreted by the salivary glands and aids lubrication and mixing of ingesta. It is widely reported that dogs lack salivary alpha-amylase, thus limiting the initiation of carbohydrate digestion in the oral cavity. However, salivary alpha-amylase has been identified in the saliva of dogs exposed to sympathetic activation, suggesting its presence could be a possible stress biomarker (Contreras-Aguilar et al. 2017) and that there may be a dietary role for this enzyme.

Taste perception occurs within the mouth from the stimulation of taste buds on the tongue, and sensitivity is identified to amino acids, nucleotides, and various organic acids, substances all abundant in animal-derived tissues and consistent with an observed canid preference for such dietary components (Kumazawa et al. 1991). Notably, dogs demonstrate a preference for sweet foodstuffs (Houpt et al. 1979; Ferrell 1984) and will often demonstrate a feeding preference for sweet-tasting materials over bitter flavors. This is likely representative of the adaptation of many canids to an omnivorous dietary strategy as scavenging and opportunistic food intake replaced hunting and prey acquisition. This is also likely to account for the occurrence of “dietary indiscretions” observed in the domestic dog, where otherwise toxic compounds, such as theobromine in chocolate intended for human consumption, can be preferentially ingested over other foodstuffs.

The canine esophagus has striated muscle only, permitting rapid peristalsis and swallowing (Stevens and Hume 1995). Mucus is secreted to permit lubrication of ingesta as it moves down the gastrointestinal tract, and movement of food from the mouth to the stomach only takes seconds (Maskell and Johnson 1993). The canid stomach is small and simple but with enormous expansion

capability to permit the ingestion of large prey items (Hume 2002) and to support opportunistic gorge feeding on large volumes of food. The stomach is where protein digestion begins, although most chemical digestion of dietary fat, carbohydrate, and protein, followed by nutrient absorption, occurs in the small intestine. The small intestine is short in length (Stevens and Hume 1995), with a significant microflora population that is increasingly linked with both gut and systemic health and can be influenced by dietary components such as prebiotic fibers (Sparkes et al. 1998).

The small intestine empties into a relatively short colon which has a key digestive role in the resorption of water and electrolytes. The microbial population within the colon is also of significance in both intestinal and systemic health and depending on dietary composition, can impact on fecal form and output. The canid cecum is typically smaller (relative to body size) than that observed in highly omnivorous species such as swine, although it is larger than observed in obligate carnivores such as felids, suggesting a proportion of cecal fermentation of digesta.

## Feeding Behavior

Feeding behavior is diverse within the Caninae subfamily and represents an evolutionary move toward a mixed dietary intake, in contrast to hypercarnivorous dietary strategies observed in other members of the Carnivora. Wild and free-living canids are often restricted in diet acquisition through availability and the fact that hunting and scavenging have an inherent energy expenditure requirement. This combined with the spatial and temporal availability of foodstuffs can impact on overall diet composition in wild and feral populations. Conversely, domesticated and managed species will often have a nutritionally consistent diet, in both content and supply. However, ancestral feeding behaviors will still be observed in such species (Bradshaw 2006).

For species that typically acquire food by cooperative hunting, gorge and intermittent

feeding is often observed, with large amounts of food ingested in a relatively short period of time and then digested over a prolonged period. This can appear as a gorge-fast cycle and is sometimes mimicked in the captive management of such species. Cooperative hunting also explains the typically rapid ingestion of food observed in canids, where competition between pack members for key resources, such as food, can be intense, and explains the social facilitation of food intake and dietary preferences often observed in canids (Lupfer-Johnson and Ross 2007).

Scavenging and opportunistic food intake are identified across canid species, including occasional hoarding behavior. This can manifest through the intake of a range of material that, for domestic and managed species, can be less than acceptable to human caregivers. In the case of the domestic dog, feeding behavior linked to the ingestion of fecal material and other waste products is often described as undesirable from both a health and human perception perspective, although such behaviors are suggestive of the evolutionary origin of these species. The domestic dog is often identified to indulge in coprophagy of their own feces, conspecific fecal matter (Hart et al. 2018), or feces from other species. While distasteful to caregivers, and often attributed to nutritional or behavioral issues, it appears that coprophagy is likely to represent an evolutionary remnant of a denning species, intended to keep the den and immediate environs clean and potentially parasite free, rather than linked to breed, gender, nutritional status, or other attributes (Hart et al. 2018).

Grass and plant eating are also widely reported in domestic dogs (Sueda et al. 2008), and while the consumption of plant material is well identified within the Caninae, plant eating in domestic dogs is often attributed to illness, digestive discomfort, or nutritional inadequacy. However, it appears that grass (and other plant material consumption) is more likely linked to natural exploratory and ingestive behaviors (Bjone et al. 2007), in addition to a preference for sweet tastes (Ferrell 1984), rather than illness or dietary deficiencies.

## Canine Nutritional Requirements

In contrast to obligate carnivores such as felids, canids are often described as facultative carnivores with metabolic and biochemical pathways and processes that have evolved to permit the biosynthesis of key biological compounds, meaning that dietary provision of animal-derived material is not always necessary. Indeed, linked with the increased humanization of domestic companion animal species, there is an increase in domestic dogs being successfully fed either a vegan or vegetarian diet (Knight and Leitsberger 2016), indicating the nutritional promiscuity of this taxonomic group.

Obligate carnivores typically demonstrate metabolic adaptation for high levels of protein consumption, limited biosynthesis of specific biomolecules, and minimal ability to metabolize dietary carbohydrate (Zoran 2002). Gluconeogenesis is critical to support the maintenance and supply of glucose levels in these species, and a diet consisting predominantly of animal material is essential for survival, also supplying key nutrients such as arachidonic acid, taurine, and pre-formed vitamin A (MacDonald et al. 1984).

Notably, taurine is often considered dispensable in canine diets where there is ingestion of adequate levels of sulfur-containing amino acids that support taurine synthesis (Kramer et al. 1995; Delaney et al. 2001) or ingestion of taurine-rich animal-derived tissue. Taurine is essential for normal somatic functions, notably ocular and cardiac. However, evidence suggests that taurine is essential in fox diets, and dog diets that are formulated to be low in protein or necessary precursor molecules (Backus et al. 2003) can produce clinical symptoms of deficiency. This has been further complicated with specific commercial diet formulations being putatively linked to apparent taurine deficiency symptoms in the domestic dog (Freeman et al. 2018), suggesting a possible nutritional value in ensuring a dietary taurine supply. Indeed, taurine supplementation is indicated for captive maned wolf (*Chrysocyon brachyurus*), a predominantly frugivorous South American canid, following

concerns about plasma taurine concentrations in animal-fed diets formulated to manage cystinuria (Childs-Sanford and Angel 2006).

In common with obligate carnivores, canids are also capable of high levels of gluconeogenesis from protein precursors, and it is well identified that the domestic dog has no specific dietary need for dietary provision of carbohydrate as a result. However, both wild and domestic canid species consume carbohydrate containing material, by both choice and opportunity. Additionally, the domestic dog has a clear genetic signature relating to the ability to digest starch, contrary to popular belief (Axelsson et al. 2013), with this ability demonstrating some breed and type differentiation. It is also recognized that a dietary intake of carbohydrate can support canine reproductive functioning (Romsos et al. 1981) and in the athletic domestic dog, for some activities, dietary carbohydrate provided in the correct form and at the correct time can support performance output and enhance recovery (Wakshlag et al. 2004).

Dietary fat and protein will be significant contributors to nutrient intake in canids consuming large amounts of animal-derived tissue, which will also provide a ready supply of other nutrients, including key vitamins and minerals. Fat appears to be a key nutrient to support canine energy expenditure and is key in the diet of domesticated, working canines (Downey et al. 1980). For domestic and managed species, nutritional provision can be easily managed and adapted to suit life stage and activity level. Indeed, key resources to support the design and formulation of diets for domestic and captive canids are based on extensive scientific research, much of it being funded by commercial pet food manufacturing companies. These guidelines are continually updated based on academic findings and are intended to ensure nutritional suitability and sufficiency is covered (NRC 2003; FEDIAF 2019). For wild and feral canids however, diet is more restricted and limited to the temporal, seasonal, and spatial availability of foodstuffs, meaning that periods of nutritional adequacy can be interspersed by periods of nutritional inadequacy.

## Conclusion

The canine diet is typically a diverse one, encompassing scavenging, omnivory, and carnivory to different extents, with a trend toward hypo- and facultative carnivory in contrast to hyper- and obligate carnivory as observed in felids. The dietary flexibility observed within canids is likely to be in part responsible for their evolutionary success and wide geographical distribution, in addition to the successful dyad developed between the domestic dog and *Homo sapiens*.

The digestive anatomy and physiology of a typical canid are simple, demonstrating few specific adaptations (such as extensive microbial fermentation and prolonged digesta retention times) required to support the digestion of plant-based material, as observed in herbivorous species. The dentition and much of the digestive anatomy are akin to a typical carnivore, although subtle alterations and adaptations are identified, notably the genetic adaption to starch digestion as observed in the domestic dog. This is in addition to the ability to synthesize some key nutrients, such as taurine, negating the absolute need for animal-derived tissues in their diet in contrast to obligate carnivores, although evidence suggests that there might be species-specific requirements.

Feeding behavior is diverse in canids, with scavenging, omnivory, kleptoparasitism, and hunting (cooperative and solitary) being observed. The flexibility to obtain nourishment via different behavioral strategies from hunting to scavenging limits reliance on the temporal and spatial availability of specific feedstuff.

The diversity observed in the dietary intake of canids is, in part, responsible for their continued success and ability to rapidly adapt to changing environmental conditions. For free-living canids, diet remains restricted by ecological factors such as season, prey/predator density, and other temporal and spatial factors such as climate and anthropogenic impacts. For species such as the domestic dog, human choices, perceptions, and control limit dietary intake in a similar way, but the nature of the human-dog dyad is recognized to have a significant impact on dietary choices made available to the dog. The risk of obesity

and associated conditions with negative links to health and welfare is significant in the domestic dog population, ironically while correlated with increasing knowledge about canine biology generally. As such, canine diet remains a critical factor in the survival and success of canids generally but also a significant topic for discussion and debate in the domesticated members of the family.

## Canine Life History

Lisa J. Wallis  
Department of Ethology, Eötvös Loránd  
University (ELTE), Budapest, Hungary

### Definition

Canine life history describes the reproduction, growth, and survival patterns for species in the mammalian Canidae, a family within the Carnivora order with multiple species, including dogs, wolves, foxes, jackals, coyotes, and other dog-like mammals.

### Introduction

The family Canidae belongs to the suborder Caniformia, and its name comes from the Latin *canis* meaning “dog.” The dog-like caniforms emerged within the Carnivoramorphia 43 million years before present (Flynn and Wesley-Hunt 2005). Three subfamilies existed, but two became extinct, Hesperocyoninae (about 39.74–15 Mya) and Borophaginae (about 34–2 Mya), and the third, Caninae (about 34–0 Mya), is the only

surviving subfamily. Using DNA analysis the surviving members of the Canidae family have been divided into a basal Caninae group (containing the gray fox and island fox) and two tribes, the Canini (true dogs) and Vulpini (true foxes) (Lindblad-Toh et al. 2005). Canidae are the most geographically widespread family of Carnivora and are found on every continent except Antarctica. For example, the red fox and the gray wolf have the most extensive range of all land mammals. Canids live in a wide range of habitats including deserts, mountains, forests, and grasslands. Canidae today include a diverse group of around 36 species ranging in size from the fennec fox (*Vulpes zerda*) measuring only 18 cm at the shoulder and the maned wolf (*Chrysocyon brachyurus*) at over 90 cm (Sillero-Zubiri et al. 2004). One particular canid, the domestic dog (*Canis familiaris*), was the earliest known domesticated animal and remains today one of the most widely kept domestic animals around the world.

### Characteristics

The body shape of all canids (in particular jackals, coyotes and wolves) is relatively similar with long muzzles, upright ears, long legs and lithe bodies adapted for chasing prey, with the exception of the bush dog (*Speothos venaticus*), raccoon dog (*Nyctereutes procyonoides*) and some domestic breeds of dog (*Canis familiaris*) (Castelló and Sillero-Zubiri 2018; Miklósi 2014). The length of the muzzle, ears, and tail can also vary significantly between species; however, the gray wolf shows the typical basal form of the family. All canids walk on their toes showing typical digitigrade qualities enabling them to move quickly and quietly. The cushioned pads on the soles of the feet and the tip of the nose are naked. The soles consist of a three-lobed central pad and a single pad behind the tip of each toe. There are five toes on the fore feet, but the pollex (thumb) does not reach the ground. The African hunting dog is the exception to this rule, as it has only four toes. The hind feet of all canids have four toes (but some

domestic dogs have a fifth vestigial toe called a dewclaw) (Mivart 1890).

Male canids possess a bone called the baculum, which supports the penis, and a structure called the bulbus glandis at the base of the penis helps to create a copulatory tie during mating. The copulatory tie is a characteristic of mating in most Canids; during mating the bulbus glandis becomes engorged with blood and locked in the contracted vagina of the female. The two animals can remain attached by their genitals for 15 min or more, during which time ejaculation takes place (Castelló and Sillero-Zubiri 2018). All young are born blind, and their eyes open a few weeks after birth.

Most canids have 42 teeth, which are adapted for cutting, crushing, grinding, and slicing and reflect their dietary habits including hypercarnivory and a more omnivorous diet. All except the bush dog (*Speothos venaticus*), dhole (*Cuon alpinus*), and bat-eared fox (*Otocyon megalotis*) have the same dental formula of three incisors, one canine, four upper premolars, and two molars in the upper jaw, and the same in the lower jaw, apart from the presence of an additional molar (Mivart 1890).

## Lifespan

The lifespan of canid species ranges from 3 to 15 years in the wild, but most species can live substantially longer in captivity (please refer to “Lifespan” section of Table 1). Mortality rates in the wild can be high due to natural sources of mortality, interspecies competition, persecution by humans (hunting and trapping for fur, meat, sport, or to be captured and kept as tourist attractions), road kills, and pathogens and parasites. Many canids come into conflict with man due to their tendency to prey on domestic livestock and wild game (Sillero-Zubiri et al. 2004).

## Foraging Behavior

Canids employ several types of foraging strategies, which are dependent on the habitat and prey

species available. Most species are generalist hunters and foragers and consume a wide range of food items including mammals, birds, fish, amphibians, reptiles, insects, plants, fruit, and seeds (please refer to the “Food” section of Table 1). Part of the Canidae’s success is due to their ability to adapt to local ecological factors. Some more specialist hunters and foragers have also evolved to exploit particular niche environments. The majority of canid species are carnivores or omnivores, with the exception of the bat-eared fox (*Otocyon megalotis*, insectivorous), Blandford’s fox (*Vulpes cana*, insectivorous and frugivorous), and pale fox (*Vulpes pallida*, herbivorous) (Sillero-Zubiri et al. 2004). Many species are solitary hunters/foragers, due to the small size of their prey; however, the larger more carnivorous species are dependent on bigger prey for sustenance and are therefore reliant on cooperative hunting efforts (please refer to the “Foraging behavior” section of Table 1). The activity patterns of each species are dependent on their prey species and, in more urban areas, human disturbance. Most species are nocturnal, crepuscular, or diurnal (Sillero-Zubiri et al. 2004).

## Social Behavior

Nearly all canid species are social animals and live together in small family groups, which consist of the breeding male and female and their current offspring. In addition, most are territorial, or have a home range, and either sleep in the open, using a den only to raise young, or are more dependent on dens on a daily basis. Territories and home ranges are maintained through driving out conspecific intruders, scent marking, and vocalizations. Some canids are solitary species and come together only to breed; others live in larger social groups called “packs,” which have the advantage of enabling them to tackle larger prey when hunting with more individuals (Sillero-Zubiri et al. 2004). Typically, the older, more experienced individuals lead the pack, and in most cases, a hierarchy is formed, and the dominant male and female are usually the only pack members to

**Canine Life History, Table 1** Information on the 36 extant species of canids listed alphabetically by scientific name. Here we include the African golden wolf (*Canis anthus*), the red wolf (*Canis rufus*), the domestic free-ranging dog (*Canis familiaris*), and the Dingo (*Canis dingo*) as distinct species, rather than subspecies. The data provides descriptions of general aspects of life history including the species scientific name, English common name, shoulder height (in mm) and weight (in kilograms (where possible divided by sex (M = male, F = female))), the current distribution of the species, the habitat types they are found in, what food they typically eat, the foraging behavior used to obtain their food, information about their social behavior, lifespan, breeding strategy, gestation length (in days), litter size (mean and range), IUCN status and population trend (taken from <https://newredlist.iucnredlist.org/>), and finally a list of sources (please see abbreviation key at the end of the table)

| Scientific name<br>Common name<br>N of subspecies             | Shoulder height/<br>weight                           | Distribution                                                                     | Habitat                                                                                                                                  | Food                                                                                                                                                                                                                    | Foraging<br>behavior                                                                                                                                                 | Social behavior                                                                                                                                                                                                                | Lifespan                                                                                  | Breeding<br>strategy                                                                                                                                                                         | Gestation<br>length | Litter size          | IUCN<br>status/pop.<br>trend     | Source<br>abbrev |

| <i>Canis simensis</i><br>Ethiopian wolf<br>2 subspecies   | 530–620 mm<br>M – 14.2–19.3 kg<br>F – 11.2–14.15 kg | Six isolated mountain ranges of the Ethiopian highlands (altitudes of 3,000–4,500 m) | Habitat specialist: Afroalpine grasslands and heathlands, prefer open areas with short herbaceous and grassland communities where rodents are most abundant       | Specialist carnivore: feed almost exclusively upon diurnal rodents and occasionally on antelopes, hares, goslings, eggs, carrion, and sedge leaves          | Preeminently a solitary rodent hunter but also a facultative cooperative hunter. Synchronize their activity with diurnal rodents          | Lives in family groups containing up to 20 individuals older than 1 year (average pack size is 6). Each pack has a well-established hierarchy | In the wild 8–10 years; one known male in Bale lived 12 years                | Monogamous cooperative breeders, dominant females suppress breeding of subordinates. Territorial: interact aggressively and vocally with other packs | 60–62 | (2–7)     | Endangered<br>Decreasing   | 1, 9      |
| <i>Cerdocyon thous</i><br>Crab-eating fox<br>5 subspecies | 368 mm<br>5.7 kg (4.5–8.5 kg)                       | Central part of South America                                                        | Marshland, savannah, cerrado, caatinga, chaco-cerrado-caatinga transitions, scrubland, woodlands, semi-deciduous gallery, Atlantic, Araucaria, and montane forest | Omnivorous: fruit, vertebrates, insects, amphibians, crustaceans, birds, carrion, cultivated fruits, domestic fowl, and refuse                              | Opportunistic predator: nocturnal and crepuscular. Hunt individually but most commonly as pairs                                           | Social groups comprise a breeding pair and 1–5 offspring (older than 1 year). Territorial during dry season                                   | Oldest recorded individual 9.2 years in the wild                             | Monogamous. Both parents rear the young                                                                                                              | 56    | 2.6 (1–3) | Least concern<br>Stable    | 1         |
| <i>Chrysocyon brachyurus</i><br>Maned wolf                | 900 mm<br>25 kg                                     | Central South America: Argentina, Bolivia, Brazil, Paraguay, Peru, and Uruguay       | Lowland grasslands and scrublands, woodland with an open canopy (cerrado), wet fields, agricultural and pasture land                                              | Omnivorous: fruits and small- to medium-sized vertebrates, birds, reptiles, and arthropods. 50% of the diet comprising plant material and 50% animal matter | Solitary hunters/foragers, but pairs have been observed to hunt together. Nocturnal and crepuscular, forage for up to 8 consecutive hours | Pairs may defend a shared territory of approximately 30 km <sup>2</sup> , although outside of mating, the individuals may meet seldom         | In captivity, maned wolves may live up to 16 years. Lifespan in wild unknown | Facultatively monogamous. Both parents have been observed to regurgitate food for the young                                                          | 60–65 | 3 (1–7)   | Near threatened<br>Unknown | 1, 10, 11 |

| <i>Speothos venaticus</i><br>Bush dog                        | 200–300 mm<br>5–8 kg                                             | Eastern Central America and northern South America, south to Paraguay, and north-eastern Argentina                  | Habitat<br>generalists. Occur near water sources. Lowland forested habitats including primary and gallery forest and seasonally flooded forest                                        | Primarily carnivorous: large rodents, small mammals, lizards, snakes, and possibly ground-nesting birds | Hunting parties consist of at least 2 individuals. Mostly diurnal                                                                                                                          | Considered the most social of the small canids living in family groups consisting of a breeding pair and their offspring, ranging from 2 to 12 individuals. Home range of 3.8 to 10 km <sup>2</sup>                                                 | Around 10 years in the wild, 13 years in captivity                               | Monogamous. Males exhibit a high degree of parental care. Dominant females suppress the estrus of daughters                                                                                                            | 67    | 3.8 (1–6)  | Near threatened<br>Decreasing | 1 |
| <i>Urocyon cinereoargenteus</i><br>Gray fox<br>16 subspecies | 300–380 mm<br>M – 4.0 kg<br>(3.4–5.5)<br>F – 3.3 kg<br>(2.0–3.9) | Central and eastern Canada, Oregon, Nevada, Utah, and Colorado in the United States south to Venezuela and Colombia | Deciduous/ pine forests, old fields, scrubby woodlands, mixed agricultural/ woodland/ chaparral/ riparian landscapes, shrub and thick brush habitats, semiarid areas, and urban areas | Omnivorous: rabbits, rodents, insects, birds, fruits and nuts, and carrion                              | Solitary hunters. More active at night than during the day. Increase their home ranges during late autumn and winter in response to changes in food resource availability and distribution | Basic social unit is the mated pair and their offspring of the year. Dens are used any time of the year but mostly during breeding season. Tree dens may be located 30 f. above the ground. Home range size ranges from 0.8 to 27.6 km <sup>2</sup> | 4–5 years in wild. However, individuals of 14–15 years are occasionally reported | Monogamous, occasionally polygynous. Pups accompany adults on foraging expeditions at 3 months. Family group remains together until the autumn, when young males disperse and females stay within proximity of the den | 53–60 | 3.8 (1–10) | Least concern<br>Stable       | 1 |
| <i>Urocyon littoralis</i><br>Island fox<br>6 subspecies      | 120–150 mm<br>M – 2.0 kg<br>(1.4–2.5)<br>F – 1.8 kg<br>(1.5–2.3) | Restricted to six of the California Channel Islands off the coast of southern California, USA                       | Habitat<br>generalist: dunes, bluffs, grasslands, sage scrub, cactus scrub, chaparral, oak/riparian woodlands, pine forests, marshes, and developed areas                             | Omnivorous: rodents, birds, lizards, insects, snails, molluscs, carrion, and fruits                     | Solitary foraging generalist. Adult foxes may also forage together on occasion. Nocturnal and diurnal activity. Skilled climbers                                                           | Breeding pairs that occupy discrete territories mean home range sizes of 0.16–3.39 km <sup>2</sup> . Not uncommon for offspring to remain in natal range                                                                                            | Up to 10 years of age in the wild                                                | Usually monogamous but extra-pair fertilization has been recorded. Dependent young accompany adults on forays                                                                                                          | 50–63 | 2.5 (1–5)  | Near threatened<br>Increasing | 1 |

| <i>Vulpes bengalensis</i><br>Indian fox                  | Unknown<br>M ~2.7–4.1 kg<br>F >1.8 kg            | Indian subcontinent (Nepal to the southern tip of the Indian peninsula) | Semi-arid, flat to undulating terrain, scrub and grassland habitats, thorn or dry deciduous forests, plains, and open scrub forest     | Omnivorous: arthropods, rodents, reptiles, fruits, and birds                                                                            | Solitary opportunistic foragers. Crepuscular and nocturnal                                                       | Basic social unit of a breeding pair formed through pair bonds that may last for several years. Hide in dens during day. Larger aggregations may exist when grown pups remain in natal group                      | In captivity, the lifespan is about 6 to 8 years      | Monogamous, but extra-pair copulations are known to occur. Both parents bring food to the pups and guard the den                                                                                     | 50–60               | 2.7 (2–4)   | Least concern<br>Decreasing  | 1, 14           |
| <i>Vulpes cana</i><br>Blanford's fox                     | 200–250 mm<br>0.8–1.5                            | Middle East and Central Asia                                            | Mountainous regions, slopes, stony plains and patches of cultivation, dry creek beds                                                   | Insectivorous and frugivorous: invertebrates, fruits and plant material, vertebrates                                                    | Almost always solitary foragers only occasionally foraging in pairs. Strictly nocturnal                          | Pairs live in territories of c. 1.6 km <sup>2</sup> that overlap minimally. Size of nightly home range average 1.1 ± 0.7 km <sup>2</sup>                                                                          | Estimated 4–5 years in the wild. In captivity 6 years | Strictly monogamous, but no real evidence of paternal care                                                                                                                                           | 50–60               | 2 (1–4)     | Least concern<br>Stable      | 1               |
| <i>Vulpes chama</i><br>Cape fox                          | 280–330 mm<br>M 2.8 kg (2–4.2)<br>F 2.5 kg (2–4) | Central and western regions of Southern Africa                          | Open country, grassland, agricultural land, lightly wooded areas, dry Karoo regions, the Kalahari, and the fringes of the Namib Desert | Omnivorous: small rodents (murids), hares, reptiles, birds, invertebrates and some wild fruits, occasionally scavenge young lambs/goats | Foraging is a solitary nocturnal activity and may gather in loose groupings to forage at an abundant food source | Breeding pair with home range of 1.0–4.6 km <sup>2</sup> . Overlapping home ranges, especially in areas where food is abundant. Shelters in burrows during the day. Comes together mainly for the breeding season | 6 years in the wild but can live for up to 10 years   | Monogamous breeding pair, mate for life. Both parents feed the pups, but the vixen is the main provider; no helpers are found at dens. Both parents will defend the pups against potential predators | 51–53               | 2.9 (1–6)   | Least concern<br>Stable      | 1               |

| <i>Vulpes corsac</i><br>Corsac<br>3 subspecies    | 300 mm<br>M – 2.75 kg<br>(2.5–3.2)<br>F – 2.1 kg<br>(1.9–2.4) | Central and<br>northeast Asia                                                      | Steppes,<br>semideserts<br>and deserts,<br>avoiding<br>mountains,<br>forested areas,<br>and dense<br>bush. breed (Bonanni et al. 2017; Cafazzo et al. 2014; Kubinyi and Wallis 2018; Sillero-Zubiri et al. 2004). Surprisingly, for some species, detailed information about their social behavior is lacking (e.g., the short-eared dog (*Atelocynus microtis*), Sechuran fox (*Lycalopex sechurae*), and pale fox (*Vulpes pallida*); please refer to the “Social behavior” section of Table 1). For other species, captive animals have provided some insight into their social systems (Sillero-Zubiri et al. 2004).

## Breeding Strategies

The majority of canid species are monogamous, having only one mate at a time, but polygyny has also been observed in some species (the chilla (*Lycalopex griseus*), bat-eared fox (*Otocyon megalotis*), gray fox (*Urocyon cinereoargenteus*), island fox (*Urocyon littoralis*), kit fox (*Vulpes macrotis*), and red fox (*Vulpes vulpes*); please refer to the “Breeding strategy” section of Table 1) (Sillero-Zubiri et al. 2004). Many are also said to mate for life, but actual data regarding this phenomenon is lacking in most species. Polygyny is likely to occur when ecological conditions are favorable, in years with high food abundance.

## Reproduction

Canids are unusual among mammals as a whole as they exhibit several reproductive traits that are uncommon. As stated previously they are typically monogamous, in almost all cases, both the male and female have been observed to provide care to the offspring, and they have reproductive cycles with lengthy proestral and dioestral phases and have a copulatory tie during mating (Castelló and Sillero-Zubiri 2018). Some species even retain adult offspring within the social group, which provide alloparental care to raise the next generation of offspring. The breeding pair typically suppresses mating in their adult offspring through behavioral means. In females that ovulate

but fail to conceive, pseudopregnancy frequently occurs, which helps to ensure maternal behavior of subordinate females. Canids are rare among mammals in that they have monoestrus cycles: a single ovulatory period followed by pregnancy (if fertilization occurs) or by prolonged diestrous phase and then anestrus (Asa et al. 2003). Most canids breed seasonally, with species in temperate latitudes responding to changes in photoperiod, and those in equatorial regions, to seasonal changes in rainfall and/or food availability. Therefore, most have only one seasonal cycle per year; however, African wild dogs (*Lycaon pictus*), fennec foxes (*Vulpes zerda*), crab-eating foxes (*Cerdocyon thous*), bat-eared foxes (*Otocyon megalotis*), and bush dogs (*Speothos venaticus*) have been observed to sometimes have a second cycle per year in the wild and/or captivity (Sillero-Zubiri et al. 2004). The inter-estrus intervals range from 8 to 10 months, which is similar to the mean interval of most breeds of domestic dog. These nonseasonal monoestrus cycles may be due to changes in photoperiod caused by living in captivity or because the first litter was lost (Valdespino et al. 2002). In terms of gestation period, small-sized canids typically require 50 days on average and larger canids around 60 days (please refer to the column titled “Gestation length” in Table 1). Litter size appears to be highly variable within and between canid species. Arctic foxes and African wild dogs have the greatest range in litter size, and Asa et al. (2003) suggested variability in litter size might be related to ecological variability (food availability and climate). Prolactin hormone levels peak in male and female canids during the spring; usually the time pups are born, which may facilitate paternal behavior (however, prolactin levels have so far only been measured in wolves, dogs, red foxes, and arctic foxes). More research is necessary on life history and reproductive traits of small canids in particular, as data is still lacking (Asa et al. 2003).

The young are usually born in a den dug by the female in order to provide warmth and protection. They are small, blind, and helpless and thus

require an extended period of care (Mivart 1890). When the young eventually begin to eat solid food, both parents, and often other pack members, may bring food back to the den and/or regurgitate food for them. They may also accompany them on short foraging trips around the den. Young canids may require 5 months to over a year before they are ready to leave their natal group, and in some species, they will remain in the pack as non-breeding helpers. Typically, small canids tend to reach puberty earlier than larger canid species (Asa et al. 2003).

## Synonyms

Canine gaits; Dog gaits; Dog locomotion

## Definition

Movement used by members of the family Canidae (e.g., foxes, wolves, jackals and domestic dogs) to traverse their environment.

The canines are species belonging to the family Canidae in the order of Carnivora. This includes foxes, wolves, jackals, and domestic dogs (Padilla and Hilton 2015; Pessutti et al. 2008). Canines are recognized for their long slender legs and digitigrade locomotion (Carr and Dycus 2016). Modifications to the axial musculature has allowed the group to move with an emphasis on speed and agility (Granatosky 2019). The greyhound dog, for example, has deep back musculature that produces a great deal of power and force, allowing the animal to partake in a rotary galloping gait (Webster et al. 2014). The canines are widely known for their diverse ecological habitats, which include, but are not limited to, coastal regions, deserts, grasslands, and the arctic. Some species, such as the red fox (*Vulpes vulpus*) and coyote (*Canis latrans*), do exceptionally well in human-modified habitats,

such as reservoirs, forest edges, and roads (Grubbs and Krausman 2009; Trehella et al. 1988). Much of the success of the canines to adapt to such a broad range of habitats comes from their generalized cranial and postcranial anatomy (Padilla and Hilton 2015; Pessutti et al. 2008). As both omnivores and carnivores, their feeding habits are no less diverse, which include, but are not limited to insects, birds, frogs, arthropods, grasses, and fruits (Pessutti et al. 2008).

## Gait Patterns in Domestic Dogs

As a result of our close interactions with domestic dogs, we have considerable knowledge about locomotion in the canines. The large morphological disparity observed within the domestic dogs reveal considerable variation in gait patterns and locomotor capabilities. Hildebrand (1968) explored symmetrical gait patterns for 37 different breeds and observed a wide variety of gaits dependent on limb length and speed. Quadrupedal gaits in canines are usually categorized as symmetrical or asymmetrical based on kinematics and then further subdivided into walking and running on the basis of either kinematics or kinetics (Alexander 2003). Symmetrical gaits occur when footfalls of the forelimb and hindlimb are evenly spaced in time (e.g., walk, pace, or trot). Asymmetrical gaits (e.g., gallop and bound) occur when the actions of the forelimb or hindlimb are unevenly spaced in time. All walking gaits in the canines are symmetrical and are defined by the sequence and coupling patterns by which animals move their limbs (Alexander 2003; Granatosky 2018). A lateral-sequence gait is one in which each hindlimb footfall is followed by an ipsilateral forelimb footfall (i.e., right hindlimb, right forelimb, left hindlimb, left forelimb). A diagonal-sequence gait is one in which each hindlimb footfall is followed by a contralateral forelimb footfall (i.e., right hindlimb, left forelimb, left hindlimb, right forelimb). Commonly during walking gaits, the forelimbs and hindlimbs are traveling together as a slightly asynchronous couplet. When the ipsilateral forelimbs and hindlimbs are traveling together, this is referred to as a lateral couplet;

when the contralateral forelimbs and hindlimbs are traveling together, this is referred to as a diagonal couplet. Very rarely do the limbs move together in perfect synchrony (Granatosky 2018).

Lateral-sequence lateral-couplet footfall patterns tend to be present in long-legged canids (e.g., greyhounds) and are assumed to be the best mechanism to prevent interlimb interference (Hildebrand 1968). However, this footfall pattern is thought to be inherently unstable, as a majority (~66%) of the stride is spent as a unilateral bipod (i.e., only two ipsilateral limbs in contact with the substrate), which tends to roll the body side-to-side throughout the stride (Cartmill et al. 2002). This instability is argued to be negligible for long-legged animals, but can be devastating for short-limbed broad-chested canines (e.g., Pembroke Welsh Corgi) (Hildebrand 1968). For these species, lateral-sequence diagonal-couplet footfall patterns tend to be more common. This footfall sequence is inherently more stable than lateral-sequence lateral-couplet gaits due to the generally low proportion of the stride spent as a unilateral bipod (~22%), and the relatively high proportion of the stride spent as a diagonal bipod (only two contralateral limbs in contact with the support) and large tripod (three widely splayed limbs in contact with the support). In general, foot positions arranged as diagonal bipods and large tripods are thought to be highly stable (Cartmill et al. 2002; Granatosky 2018).

At higher speeds, canines adopt running gaits. The trot, amble, and pace are symmetrical running gaits observed in canines and the use of these specific movement patterns is largely driven by limb length (see Hildebrand 1968). All running gaits include some period of the cycle in which no feet are touching the ground (i.e., an aerial phase). In trotting, diagonally opposite feet move in phase with each other; in pacing, the two feet on the same side of the body move in phase with each other; and in ambling, the four feet move at roughly equal intervals, in the same order as in walking. Most canines trot when travelling at moderate speeds, but pacing is common in longer limbed species (Hildebrand 1968). Some canines (e.g., the greyhounds) are known to reach speeds of over 64 km per hour. This remarkable speed can

be attributed to its use of the rotary gallop, also referred to as a double suspension gallop (Bertram and Gutmann 2009; Granatosky 2019; Usherwood and Wilson 2005). The double suspension gait is a four-time, asymmetrical gait where the feet fall in a circular sequence around the body, and gets its name from the two aerial phases: a gathered aerial phase where the back is flexed and the hindfeet pass in front of the forefeet, and an extended aerial phase where the feet are stretched away from the body and the back is extended (Bertram and Gutmann 2009; Hudson et al. 2012). When running competitively, the greyhound is in the air 75% of the time (Granatosky 2019).

Gait patterns in domestic dogs are often used to determine health and check for any orthopedic (e.g., cruciate ligament tear, hip dysplasia, patellar luxation) or neuromuscular pathologies (e.g., degenerative myelopathy; Carr and Dycus 2016; DeCamp 1997). Lameness that occurs within the forelimbs or hindlimbs in dogs can be witnessed upon gait evaluation. Abnormalities of the gait can be identified as limping, skipping and staggering, favoring one side over the other, showing

weaknesses or avoidance in walking. When evaluating gait in dogs, several points must be kept in mind. Among them are selecting a platform that is flat and smooth, examining both the walk and trot, observing the dog from various viewpoints, and looking at the dog's specific characteristics if it is a performance or a working dog (Carr and Dycus 2016).

## Comparisons with Wild Canids

Overall, the quadrupedal gait patterns of wolves, coyotes, fox, and other canids are largely consistent with the patterns discussed above, and much of the variation in gait sequence is attributable to limb length (Fig. 1). Therefore, this chapter will not discuss limb phase of these other species individually. However, data on energetic expenditure does reveal interesting patterns in the wild canids compared to their closely related domestic cousins and other similarly sized animals. The wolf, coyote, fox, and dog exhibit an aerobic performance capacity that is approximately three

**Canine Locomotion, Fig. 1** The relationship between limb length to body mass ratio [i.e. limb length (mm) divided by cube root of body mass (g)] and limb phase (i.e., percentage of stride interval that forelimb footfall follows hindlimb footfall on the same side) for five

species of canine [yellow = dhole (*Cuon alpinus*); white = golden jackal (*Canis aureus*); green = gray wolf (*Canis lupus*); blue = blue-maned wolf (*Chrysocyon brachyurus*); black = red fox (*Vulpes vulpes*)]

times greater than animals of equivalent size (Bryce and Williams 2017). Arguably such energetic capabilities are adaptations for dealing with active long-distance hunting and large home range size (e.g., 259–1676 km<sup>2</sup> in wolf populations, Mattisson et al. 2013). Wolves have narrow chests and powerful backs and legs that allow for incredible stamina and speed. Wolves can cover several miles trotting at a speed of 10 km per hour and have been known to reach speeds approaching 64 km per hour during a chase. Wolf hunts can either last minutes or hours depending on whether attacks are successful or not (Muro et al. 2011).

This remarkable energetic capacity in wolves has been attributed to differences in body posture observed among the wild canids. Bryce and Williams (2017) noted that wolves tend to have a stance of a flat topline and hindlimbs positioned closer to their center of mass resulting in a small obtuse hip angle (Fig. 2). Northern breeds of canines, such as the Alaskan malamute, exhibit a near identical hip angle to the wolf even though these canines have a more upright stance. When looking at other canines, such as the hound and retriever, there is considerable divergence in locomotor posture with respect to their genetic descent. Hounds and retrievers tend to have an even more pronounced upright stance and significantly wider hip angles compared to wolves and northern breeds. This difference in stance may lead to a difference in mechanical advantage. A more upright stance may allow for a more efficient way of placing load on hindlimbs and muscles. The northern breeds tend to have a lower cost of transport when trotting and galloping compared to the hound and retriever (Bryce and Williams 2017).

As a consequence of the wide-ranging behavior of the wild canines, locomotor cost represents a large proportion of overall daily energy expenditure. Covell et al. (1996) reported daily energetic expenditure of free-living swift foxes (*Vulpes velox*) on shortgrass prairie in Colorado in relation to air temperature, daily activity period, and movement rate. They observed that the energy expended in locomotion is a substantial portion of the swift fox's field energy expenditure

**Canine Locomotion, Fig. 2** Comparative hip and topline angles of (a, e) gray wolves, (b, f) northern breeds, (c, g) hounds, and (d, h) retriever dogs. Bryce and Williams (2017) noted that (a–d) hip angles tend to be more acute and (e–h) topline angles more obtuse in wolves and northern breeds compared to hounds or retrievers. These differences in body posture have been posited to result in lower locomotor cost of transport in wolves and northern breeds. Figure modified from Bryce and Williams (2017)

(~21% of total daily energy expenditure), especially in winter. Arguably, the large daily travel distances covered by this species during the winter months (~18.5 km) when food is scarce account for such high energetic demands.

### Anthropogenic Influence on Canine Locomotion

As a result of the long history between humans and domestic dogs, canine locomotor capabilities have been exploited in terms of both work and sport. Perhaps most notable is greyhound racing, which is a competitive, organized sport in which bets are placed as greyhounds run around a track. Greyhounds are thought to be one of the oldest breeds of dogs and were bred to hunt by outrunning their prey (Thompson 2003). Through

artificial selection, greyhounds have acquired many anatomical features that allow them to reach great speeds (Williams et al. 2008a, b). Greyhounds have long, powerful legs, a deep chest, a highly flexible spine, and a slim build. The greyhounds' heart is larger than similarly sized breeds and pumps blood with higher levels of red blood cells than other breeds. As red blood cells carry oxygen, this higher level allows the hound to move large quantities of oxygen faster from the lungs to the muscles (Herrmann 1926). These attributes separate greyhounds from other dogs, specifically dogs that do not regularly participate in intense physical activity.

The ability to perform at this capacity is an extraordinary feat, but it also puts considerable strain on the body. There are many health risks and dangers that are associated with maintaining dogs in racing condition, and many former racing dogs develop complications years later post-retirement. Greyhounds are notorious for physiologic systolic murmurs associated with high aortic velocity, and large cardiac dimensions (Lord et al. 2007; Marin et al. 2007). The high aortic velocity of the blood being passed through the heart to supply the extremities with oxygenated blood causes valve failures. A popular practice among breeders and caretakers for the greyhounds that participate in these races is feeding them raw meat. A raw meat diet has been shown to provide more energy and stamina for canines. For such reasons, it is a staple diet for greyhound race dogs to create an optimal competitor. A negative outcome of this practice is the spreading of *Salmonella enterica* to not only the dogs but to humans as well (LeJeune and Hancock 2001).

Dog sledding has been a popular mode of transportation for northern region individuals in the wintertime (Cary 2009). This means of travel has further progressed into becoming a competitive sport. "Sled dogs" is a general term referring to a group of dogs primarily chosen as the "engines" for dog sledding. These breeds are, but are not limited to, Malamutes, Siberian Huskies, Inuit/Eskimo dogs, and Alaskan Huskies (Cary 2009; Huson et al. 2012). Sled dogs are bred for strength, speed, endurance, intelligence, and willingness to follow orders. Each specific breed of dog in the

group when dog sledding has a specific role. There are freight dogs and race dogs, which have different attributes that contribute to their success and efficiency (Cary 2009). Dogs are bred solely on potential athletic ability, which encompasses numerous factors, such as quickness, efficient gait, pulling strength, and endurance (Huson et al. 2012). Though the sled dogs have become accustomed to this activity and climate, there are many health risks that coincide with such vigorous activities in these harsh climates. It has been demonstrated that such intense exercise can lead to oxidative stress that may in turn lead to other more life threatening illnesses such as cancer, Alzheimer's disease, and heart disease (Van Citters and Franklin 1969). Oxidative damage is a never ending complication for sled dogs that are constantly exercising and training for long arduous sled dogs (Hinchcliff et al. 2000).

## Conclusion

As a result of adaptations to diverse ecological habitats in wild canines and selective breeding in wild dogs, canine locomotion is exceptionally diverse and well-studied. Canines deal with higher than usual energetic demands during locomotion, which may stem from dealing with active long-distance hunting and large home range size. Canines have also adopted a number of gait patterns that prevent limb interference and maximize stability, ultimately reflecting upon their body frame and limb length (Hildebrand 1968). Lateral-sequence lateral-couplet footfall patterns are observed in long-legged forms like the greyhound, while short-legged breeds like the Pembroke Welsh Corgi show use of lateral-sequence diagonal couplet footfall patterns. Observing canine gaits provides information about their orthopedic and neuromuscular health. As a result of the long history between humans and domestic dogs, canine locomotor capabilities have been exploited in terms of both work and sport. Most notable are greyhound racing and dog sledding. These sports put considerable physiologic demands on the dogs and there are a myriad of health problems observed even after the animals are retired.

## Canine Morphology

Jacqueline Boyd

Skinner's Pet Foods, Stradbroke, UK

### Synonyms

Architecture; Canine shape; Canine structure; Form

### Definition

Canine morphology refers to the size, shape, and structure of members of the Canidae family. Morphology also relates to the form and function of constituent parts of an animal and will consider the general anatomy and physiology of the organism in question. General canine morphology is representative of evolutionary ancestry and functionality, with species-specific variations associated with adaptation to specific ecological niches and selection pressures.

## Introduction

Canine morphology considers the shape, size, structure, form, and function of members of the Caninae subfamily. The mammalian order Carnivora includes the Canidae family which consists of three subfamilies, two extinct (the Borophaginae and Hesperocyoninae), and the extant Caninae (Miklosi 2015). Canines belong to the Caninae and have a typical body plan described as “dog-like,” quadruped with athletic, slender bodies, elongated muzzles, upright ears, and locomotory ability suited to hunting and prey acquisition, although there are some exceptions that demonstrate more distinctive species-specific morphology. The domestic dog (*Canis lupus familiaris*), in particular, demonstrates a vast morphological diversity.

## The Caninae

The Caninae subfamily includes more than 36 species including foxes, coyotes, dingoes, wolves, jackals, and the domestic dog (Wang and Tedford 2007). The general morphology of these species is largely similar and is indicative of their shared taxonomic ancestry, although the gray wolf (*Canis lupus*) and the domestic dog are acknowledged to be particularly close on both a taxonomic and genetic basis, despite morphological differences in overall body shape, size, and other physical and behavioral attributes. Wild and free-living canids are terrestrial, denning species, often crepuscular or nocturnal in their habits, and can be either highly social, pack-hunting species such as the wolf or more solitary like the fox.

Canids exhibit a wide geographical distribution and occupy several specific ecological niches on every continent, except Antarctica and some islands (Clutton-Brock 1995). Some species such as the red fox (*Vulpes vulpes*) and the gray wolf (*Canis lupus*) have an extensive global range, suggestive of biological and evolutionary success, in addition to the fox (and the domestic dog) being introduced to new environments by humans. This distribution pattern

means that canine body size and bodyweight are diverse, but the typical body plan is largely consistent across different species and fulfils the classification characteristics of their membership of the class Mammalia and the order Carnivora. Notably, all canids possess the characteristic carnivore carnassial apparatus and other dentition typical of a carnivore, and dog skulls are widely accepted as representative of a “typical mammalian carnivore” for educational purposes. In addition, the basic skeletal system of canids, their sensory capabilities, and fundamental locomotory ability remain largely consistent across species. Senses relate specifically to enhancing prey locating skills, with forward facing eyes, adapted to detect movement, even in reduced light, highly sensitive hearing for prey detection, and a highly developed and sensitive olfactory capacity.

The Canidae family has been further subdivided based on genetic analysis into two “tribes” (the Canini or true dogs and the Vulpini or true foxes) and a basal Caninae group (containing the island fox and the gray fox; Lindblad-Toh et al. 2005). Members of the Canidae are thus numerous and range in size from the small fennec fox (*Vulpes zerda*) to the relatively large maned wolf (*Chrysocyon brachyurus*), with the domestic dog being an especially phenotypically diverse member of the Canidae.

Indeed, canine morphology is particularly interesting when considering the domestic dog, which is considered to be one of the most phenotypically and morphological diverse mammalian species (Boyko et al. 2010). This diversity is a consequence of intense anthropogenic artificial selection pressures based on physical appearance, behavior, and/or morphological functionality. Consequently, the domestic dog demonstrates a wide diversity in breed types and forms, with the physical structure and overall appearance of specific breeds being phenotypically constant and characteristic, in order to meet national and international “breed standards.” These breed standards are published criteria by which dogs can be identified as specific breeds and identify both desirable and undesirable characteristics for the form and function of individual breeds. Adherence to some specific standards,

combined with intense artificial selection for characteristics attractive to humans, has had some unfortunate consequences for health and well-being and is in distinct contrast to the consistency in morphology that is characteristic for wild, free-living, and feral canids.

## Canine Morphological Characteristics

The morphology of wild and free-living canid species is remarkably consistent. The body is typically slender, athletic, and of a moderate size, with canids often being categorized as mesocarnivores, based on morphology rather than the proportion of animal-derived tissue in their diet. Indeed, canids that tend toward a hypocarnivorous dietary strategy tend to be smaller in physical size, than forms commonly described as hypercarnivorous, a possible consequence of the energetic demands of predation and hunting (Carbone et al. 2007) and consistent with the evolutionary move toward larger body size in more predatory species (Van Valkenburgh et al. 2004).

The canid ears are often pricked and erect, the legs are long, and they have a tail that can be used for inter- and intra-species communication (Leaver and Reimchen 2008), through movement, carriage, and overall position. Tail morphology is diverse in the domestic dog, and carriage of the tail can vary as a result. Selective breeding has resulted in tails that can be curled, corkscrew, straight, or even absent. Surgical removal of either the full or partial tail length (docking) is occasionally conducted for prophylactic purposes in working domestic dogs, to prevent tail injuries (Lefebvre et al. 2007). Tail docking is occasionally conducted for cosmetic or visual preference purposes, as is ear “cropping,” although these are increasingly viewed as unacceptable morphological mutilations. It is often considered that the wolf demonstrates the typical canine physical form, although, clearly, individual species will show divergences in terms of physical height, muzzle length, ear shape, and tail length (Castello and Sillero-Zubiri 2018).

## Skull Morphology

A distinct cranial morphological characteristic of canids that is useful for classification and taxonomic purposes, including consideration of the fossil record, is the anatomy of the middle ear, located in the basicranial region (Wang and Tedford 2007). The bulla chamber of the middle ear is a bony area that protects the inner ear, and it ossifies in different ways. Canids have a characteristic inflated endotympanic bulla, divided by a partial septum, and there are characteristic locations of the internal carotid artery. These cranial characteristics have been retained through canid evolutionary history (Wang and Tedford 1994).

The domestic dog has a diverse variation in skull morphology, with diversity across different breeds and types, greater than that observed between different canid species (Wayne 1986a). The diversity observed in skull morphology in the domestic dog contrasts dramatically with the fact that the size and shape of the skull for wild canids are typically consistent for individual species and are in accordance with their dietary and ecological niche. Skull shapes are generally classified as mesaticephalic (medium length muzzle), dolichocephalic (extended muzzle length and narrow skull base), or brachycephalic (shortened muzzle length and broad skull base). Mesaticephalic is often regarded as closest to the basal, ancestral skull shape, and is the shape often identified as the typical mammalian carnivore. Brachycephaly and the popularity of dog breeds exhibiting this morphological characteristic have been linked to a human preference for neotenized canine facial forms that may resemble the human face (Archer and Monton 2011). Indeed, a shortening and widening of the dog skull have been more generally linked to the domestication process, concurrent with crowding, displacement, and reduction in the size of teeth (Clutton-Brock 1995).

Artificial selection in the domestic dog, for specific traits viewed as desirable, particularly relating to morphology, has resulted in a consistent, sustained, and significant alternation in skull shape (Drake and Klingenberg 2008). The alteration in skull shape has functional, aesthetic, and also welfare consequences for the domestic dog (Sandøe et al. 2017).

## Dentition

Canine dentition represents the general pattern observed in most carnivores, with elongated canines, small incisors, and a carnassial apparatus (De Muizon and Lange-Badre 2007). There are typically 42 permanent teeth and a dental formula of 3142/3143, a useful classification tool which includes unmodified molars and a greater number of teeth than observed in many obligate hypercarnivorous members of the Carnivora, such as felids. The carnassial apparatus is a dental signature of carnivory, although molars located caudally in canids often show an increased palatine surface for enhanced ingesta grinding and processing. Consistent with individual dietary niches, some canids will demonstrate dental adaptations toward hypercarnivory, with such species demonstrating large, strong premolars that are capable of breaking bones to acquire extra nourishment (Werdelin 1989).

## Jaw Morphology

The jaw of canids is characteristic in being limited in lateral movements. This supports the dentition and dietary ecology, toward cutting and shearing through ingested material, but also limits any prolonged grinding and chewing capacity (Kim et al. 2018). Bite force is important to support dietary intake and is generated by interactions between the muscles of the jaw, the temporomandibular joints, and the teeth. The skull size, shape, and the overall bodyweight impact on the bite force measured in the canine jaw, and bite force increases as skulls change from a dolichocephalic to a more brachycephalic shape (Ellis et al. 2009). This is a clear indication of the link between morphological form and functionality.

## Limb Morphology

As terrestrial species, canids demonstrate a morphology consistent with extensive locomotory ability. This is essential for food/prey acquisition, maintenance of territory, mate finding, and accessing other biological resources. Locomotion is cursorial, efficient, and athletic, supported by an athletic morphology. Limb morphology is extremely similar across canid species, and there is typically little variation between domestic dogs

and wolf-like species of a similar size (Wayne 1986b). There are however subtle differences in the fundamental skeletal morphology of limbs between dogs and wild fox-like species (Wayne 1986b), likely linked to developmental aspects. Canid limbs are characteristically elongated in the distal segments (metapodials, tibia-fibula, and radius-ulna) leading to an overall limb elongation (Wang and Tedford 2007).

Canids are digitigrade, meaning they effectively walk on their toes, and non-retractable claws permit adaptation to different terrestrial surfaces. The metapodials are lifted, in contrast to the more primitive plantigrade stance of ancestral canid forms such as the miacids, and permit an increase in stride length and shock absorption during locomotion. Digitigrade species have long carpals and tarsals, plus large, cushioned metacarpal pads (Miao et al. 2017). The metacarpal pads constitute cushioned soles, with a central pad and a pad behind each toe, of which there are five on the forelimbs (although the fifth toe is located higher up the limb and rarely touches the ground in normal locomotion) and four on the hindlimbs, although the domestic dog occasionally has a fifth, vestigial toe on the hindlimbs. Metacarpal paw pads aid in the management of ground reaction forces (GRFs) during locomotion, to protect the musculoskeletal system from impact (Whittle 1999) and reveal specific anatomical multilayer features to attenuate GRFs (Miao et al. 2017).

### **The Domestic Dog: Breed-Specific Morphology**

In considering canine morphology, the vast diversity of phenotypic morphology observed in the population of the domestic dog must also be acknowledged. The origins of the domestic dog remain subject to much scientific investigation and debate, but the process of their development, evolution, and domestication is estimated to have commenced some 20,000 to 40,000 years ago (Botigue et al. 2017), from a common wolf-like ancestor. The process of domestication is likely to have been a combination of human-directed

selection of specific individual animals and “self-domestication” by the animals themselves. The domesticated dog now maintains some characteristic canid features and traits but also displays altered behavioral and morphological characteristics, consistent with requirements of the human-dog dyad and associated selection pressures.

The diversity of cranial morphology in domestic dogs exceeds that observed in the Canidae family (Wayne 1986a), and there is similar diversity in terms of overall body size, shape, limb length, and fundamental form. This morphological diversity is a consequence of evolution and anthropogenic artificial selection pressures based on physical appearance, behavior, or morphological functionality. Many morphological variants observed in the domestic dog population are congruent with human desires for neoteny and human-like features in the species they share time and space with.

The diversity observed in specific breeds of the domestic dog are in part a consequence of adherence to breed standards, and changes in specific breeds have been directly attributed to desirable features detailed in these descriptive standards (Drake and Klingenberg 2008). Concurrent with the desire to artificially select animals for their “fit” to specific descriptive requirements is the potential for genetic issues arising from population bottlenecks, founder effects, genetic drift, inbreeding events, increased homozygosity, and restricted gene pools. All of these factors can give rise to specific genetic conditions that can produce morphological variations and are identified in other restricted breeding populations (Millien 2006).

The increase in the occurrence of specific genetic conditions linked to morphological variations can lead to an increase in the occurrence of specific inherited disorders capable of impacting on health, well-being, and longevity. For example, chondrodystrophy and chondrodysplasia are desirable morphological characteristics in several breeds of dogs, presenting as a shortened limb phenotype, but are also linked with intervertebral disk disease, a painful and potentially life-limiting condition (IVDD; Batcher et al. 2019). Genetic analysis and screening can be successfully

utilized in the selection of individual animals for inclusion in breeding programs, to limit the continuation of genotypes associated with deleterious consequences linked to otherwise desirable morphological traits.

Similarly, the increased popularity of dog breeds with a brachycephalic morphology (The Kennel Club 2020) such as the French bulldog, has raised concerns about welfare. Brachycephaly is associated with a range of disorders, notably ocular, dental, and respiratory (Packer et al. 2015), that impact on canine health and well-being. These extreme and exaggerated morphological features are attributed both to desirable breed standard characteristics (Asher et al. 2009) and human preferences (Packer et al. 2017), despite potential negative consequences for the individual animal.

Notably, morphological diversity is often observed to be greatest in breeds typically considered to be “companion breeds,” less in breeds selectively bred for working capacity, where functionality rather than appearance is critical and is most stringent for wild, free-living, and feral species (Drake and Klingenberg 2010). This observation is of critical importance in linking morphology with functionality. Certain breeds of the domestic dog are interesting to consider in terms of their intrinsic biological functionality as opposed to their functional and aesthetic purpose as companions for humans, especially where significant morphological deviations from the basal canid morphological form have been associated with significant health and well-being concerns.

## Conclusion

Canine morphology considers the body form of members of the Caninae subfamily, which includes a number of wild species and the domestic dog. While overall body size is divergent across canids, the typical basal morphological form is relatively consistent and is congruent with the typical canine life history, locomotion, dietary ecology, and terrestrial habitats. Particular morphological characteristics such as dentition and the structure of the middle ear are maintained

across different species and represent key classification tools. However, morphology can be diverse, especially in the domestic dog, where exaggerated and extreme phenotypes appear to be linked with intense anthropogenic selection for physical characteristics linked with aesthetic preferences. This selection has resulted in a hugely diverse range of morphological features, some of which are linked with negative consequences for individual animals. The effect of artificial selection pressures on driving morphological diversity in canids, compared to natural selection pressures that are likely to drive morphology toward biological functionality and success, is of significant interest in considering overall canine morphology.

## Canine Navigation

Jacqueline Boyd  
Skinner's Pet Foods, Stradbroke, UK

## Synonyms

Migration; Movement; Travel; Wayfinding

## Definition

Canine navigation refers to the process or activity of how members (either individuals or populations) of the family Canidae identify their position both temporally and spatially, and

then move to follow a given route, typically to access key biological resources such as water, food, or reproductive opportunities.

## Introduction

Navigation is the process by which an organism identifies its location in time and space and then uses that information to permit specific movement. The ability to move in a specific direction is essential to access key biological resources such as water, food, and reproductive opportunities. Consequently, movement and navigation within a given environment are essential for survival. Navigation is also critical for species that migrate, defined as a regular, long-distance movement toward a different location, and is observed across the animal kingdom, in both terrestrial and aquatic species.

The ability of species to successfully, precisely, and consistently navigate both over long distances, around or to objects, or the ability to orient to moving objects has long been poorly understood. However, the biological processes and environmental cues that individual species employ for navigation purposes are gradually being elucidated, and similar mechanisms are being identified in a wide array of species, from arthropods to mammals, including members of the family Canidae, such as the domestic dog, *Canis lupus familiaris*.

In order to navigate, environmental information and behavioral cues are integrated by an organism and then support directed movement to access biological resources. Animals move for several reasons, and movement is an essential process for both individual and overall population survival. Movement, whether over short distances or as more prolonged and defined migrations, permits and enhances access to key resources that can fluctuate seasonally or otherwise in time and space, such as food and reproductive opportunities (Dingle and Drake 2007).

Migration, and thus the ability to successfully and accurately navigate during migratory processes, facilitates evolutionary processes through the movement of individual animals and whole

populations, with the transfer of genetic material, acquisition of nutrients, and even movement of pathogens. Indeed, annual animal migrations have been identified to be of significance in ecosystem stability and biodiversity (Bauer and Hoyer 2014), although migration can also be a biologically demanding process, with the ability to navigate in time and space and having enough energy provision to support that movement, being critical for biological and evolutionary success.

**Canine navigation** specifically refers to how members of the Canidae family orient themselves spatially and temporally, integrating environmental stimuli and other behavioral cues. The family Canidae (from the Latin “*Canis*,” meaning dog) includes a wide lineage of species, including the domestic dog, wolves, foxes, coyotes, dingoes, jackals, and other extant doglike mammals. While canids do not specifically migrate in a seasonal fashion, they are typically social animals that have defined home ranges and territories of sizes representative of prey density. On this basis, movement within a territory will be observed to both follow prey species and access other important resources. Indeed, wolves have been acknowledged to migrate when their prey species are highly migratory, unless there is the presence of alternative prey (Mech and Boitani 2003).

## The Biology of Navigation

Navigation refers to the ability of animals to move successfully and is underpinned by a range of sensory abilities linked with the ability to identify and respond to specific cues, including light, position of the sun and stars (Wiltschko and Wiltschko 2015), circadian rhythms, specific geographical and visual landmarks, magnetic fields, echolocation, and scent. In some cases, movement and migration appear to be instinctive, and for others, it is learned or socially facilitated, leading to the term “collective navigation” (Berdahl et al. 2018). Navigational abilities are required in search of essential biological resources, and successful navigation skills are critical to support short-term and long-term locomotion toward resources and in the case of many canid species,

for awareness of and movement around and within specific territories. This is of relevance in highly territorial pack species such as the gray wolf (Mech and Boitani 2003).

Within the natural environment, individuals that can also effectively navigate to specific targets (e.g., prey), around obstacles, take detours, and reduce journey lengths are likely to have enhanced evolutionary value via ease of food and mate finding and/or a reduced predation risk or pack challenge. However, the ability to detour remains undetermined if it is a consequence of a mental awareness and mental representation of the environment or a “cognitive map” (Nesterova and Hansen 2009). A cognitive map provides a representation of the environment that an animal can access, in order to spatially navigate and orient successfully. It is likely that in such situations, an integration of different navigational tools is essential. The integration of multiple sources of information, including associative learning, permits navigation overall.

Indeed, several different sources of information are utilized by animals to support navigation for migration, prey finding, homing abilities, or simply moving within and around territories and habitats. The process by which animals navigate has been extensively investigated in a range of species, with different specializations identified. There also appears to be a combination of innate and learned abilities in terms of avian navigation skills (Wiltschko and Wiltschko 2015), and this is likely to be consistent in other species also. Indeed, species demonstrating significant navigational ability combine several different specific sensory mechanisms to ensure successful wayfinding. Considering the potential for both innate abilities and learned skills, the ability of the domestic dog to learn from other species, notably via human behavioral cues (Hare and Tomasello 2005), makes for an interesting consideration of joint navigational skills.

## Canine Navigation

Canids are widely distributed geographically and are found on all continents except for Antarctica.

The diverse habitats and environments in which canid species are found necessitate a range of adaptive abilities for both individuals and groups to orient in time and space. This is further complicated by the diversity of canid species, from wild examples such as the gray wolf (*Canis lupus*) to the domestic dog, and the respective selective pressures applied to species, based either on natural selection from environmental pressures or artificial, anthropogenic selection in the case of the domestic dog. The domestic dog is typically tightly managed in its locomotory freedom by human caregivers, with their territory and home range defined by anthropogenic factors. Feral and abandoned domestic dogs demonstrate distinct spatial and temporal resource use, likely because of prior behavioral consequences of human contact (Daniels and Bekoff 1989). Consequently, canine navigational abilities are likely based on an awareness and mental representation of the physical environment from specific environmental cues, in combination with genetic predisposition and developmental and prior behavioral experiences.

## Path Integration

Path integration (also known as “dead reckoning”) is one method of navigation whereby an animal identifies current direction and location based on a specific reference point. Path integration is one of the most primitive navigational systems and underpins other, more complex strategies, although it appears to be significant for short distances only, due to cumulative errors in direction (Seguinot et al. 1998). Path integration as a navigational tool has been identified in a range of species and typically involves the integration of different sensory systems, even in the absence of visual or other external landmarks, although visual landmark recognition may be involved in the development of cognitive “maps” (Collett and Graham 2004). Indeed, visual recognition of landmarks for navigation is, at least in part, employed by a range of species including birds, insects, and mammals, including humans, for navigation. Path integration to a target has been demonstrated in domestic dogs (Seguinot

et al. 1998), even in the absence of visual stimuli (Cattet and Etienne 2004). This suggests the possible functional importance of path integration as a navigational tool for canids to reach specific targets (e.g., prey) even via detours, by incorporating somatic signals about direction and movement, for example, from the vestibular system, rather than a reliance on visual, olfactory, or auditory cues.

## Navigation by the Sky

The position of the sun and other celestial bodies including stars and polarized light is also exploited for navigation and is dependent upon the presence of an internal “body clock” in the regulation of circadian rhythms. Indeed, the African dung beetle (*Scarabaeus zambesianus*) navigates using polarized patterns from moonlight (Dacke et al. 2003), combined with the location of stars for navigation, in common with birds, seals, and humans (Dacke et al. 2013). It is likely that canids will also integrate circadian signals, specifically light-dark cycles and internal body clocks as part of their navigational arsenal. Evidence suggests that feral dogs are most active during crepuscular and nocturnal periods of time and are similar to wild canids with a bimodal activity pattern (Boitani et al. 2007), although specific navigational abilities during those times are yet to be fully elucidated.

## Olfaction and Navigation

The olfactory ability of canid species is significantly greater than that of humans with the olfactory epithelium in dogs reaching up to 150 cm<sup>2</sup> in contrast to the typical human olfactory epithelial surface area of approximately 5 cm<sup>2</sup>. Consequently, olfaction is a major sense in canids and is an important form of intraspecific communication, which might also have an impact upon navigational ability.

For example, territorial marking via urination is common in dogs, coyotes, and wolves as well as signaling information about individuals and

their sexual status. Scent marking provides a long-lasting indication of the presence of individuals and populations (Bekoff 2001; Mech and Boitani 2003) and thus provides an opportunity for individuals to successfully navigate around or within a specific territorial area, in addition to determining the potential age of the deposition, through recognition of odoriferous deposits.

Interestingly, pigeons appear to utilize olfaction as an additional navigation cue (Ioalè et al. 1990). This finding is also of significance in considering canine navigation, given the olfactory sensitivity of canid species, although evidence suggests that in specific tasks, dogs do not rely on olfactory cues alone (Szetei et al. 2003), again supporting the integration of different strategies for successful navigation.

## Magnetic Fields and Navigation

The magnetic field of the earth is a particularly consistent environmental feature (Skiles 1985), unchanging based on season and light level, and is almost universally present, providing a source of positional information (Lohmann et al. 2007). Consequently, the earth’s magnetic field is exploited by a range of species for navigation, from bacteria to vertebrates (Wiltschko and Wiltschko 2015). Homing pigeons (*Columba livia*) demonstrate sensitivity to the earth’s magnetic field and use it, in combination with other cues such as olfaction for navigation (Ioalè et al. 1990; Walcott 1996).

Two types of positional information are supplied by the magnetic field, the simplest being compass or direction information that permits consistent movement in a specific direction. The ability to utilize compass or direction information supplied by the earth’s magnetic field has been identified in invertebrate, avian, and other vertebrate species (Wiltschko and Wiltschko 2015; Johnsen and Lohmann 2005; Lohmann et al. 2007). The second type of information that is supplied is in effect a “magnetic map” to permit navigation via the determination of geographical location, in the same way that humans might utilize GPS technology.

It is likely that species undertaking significant migrations such as the loggerhead sea turtle (*Caretta caretta*) use a combination of both compass and magnetic map information for consistent and successful migration (Arens and Lohmann 2004). There is also the intriguing evidence supporting the notion that species have both innate, inherited navigational abilities via instinctive responses to magnetic fields, as well as learned and experiential knowledge as a result of associations with visual and other landmarks (Giurfa and Capaldi 1999; Lohmann et al. 2001). This may also apply to canines in their navigational abilities and associated learning capacity.

Magnetoreception is essential to detect magnetic fields and it appears that two mechanisms exist in animals. Some fish and bird species that migrate have been shown to have magnetite particles located within their heads, suggesting the importance of detecting the earth's magnetic field for navigation (Begall et al. 2013). The second mechanism appears to be linked to cryptochromes, a group of blue-light absorbing flavoproteins that can be found in the retina and are involved in the circadian clock (Nießner et al. 2016). Indeed, cryptochrome 1, which appears to be like the version of the retinal receptor of the light-dependent magnetic sensing compass found in birds, has been identified in the cone receptors of members of the Mustelidae, Ursidae, and Canidae families and some primate species. Cryptochrome 1 has been postulated to be involved in the detection of magnetic fields and thus contributing to an ability to navigate (Nießner et al. 2016). This potential, linked with evidence that other canid species including the red fox (*Vulpes vulpes*) and the domestic dog appear to demonstrate degrees of magnetic alignment (Hart et al. 2013; Begall et al. 2013), supports the notion that geomagnetic fields may also be useful for canine navigation.

## Spatial Navigation in Canids

Spatial navigation is the ability to move specifically within an environment to locate biological

resources. The domestic dog is credited with many high-profile news stories of lost dogs apparently successfully making their way “home,” sometimes over vast distances and after prolonged periods of times (Boyd 2016). This apparent skillful spatial navigation, however, does not appear to be universal, especially when considered alongside the number of dogs who become lost and fail to successfully return “home.”

The ability to navigate in space is underpinned by two main strategies: egocentric strategies and allocentric strategies. Dogs appear to utilize a combination of both strategies in navigating, combined with visual, auditory, and olfactory stimuli from the environment. Egocentric strategies involve the awareness of where the body is in relation to environmental information and is useful when environmental cues are absent. Dogs also appear to be able to identify location by path integration which is achieved without environmental cues. Instead, there is the integration of information including distance traveled, directional changes, and speed, as identified in studies that removed visual and auditory stimuli from dogs (Cattet and Etienne 2004).

Allocentric navigational strategies consider the location of specific objects in time and space and appear to be predominantly based on visual awareness of specific spatial landmarks and beacons that provide positional information. Indeed, visual landmarks also appear critical for the development of human navigational and wayfaring skills (Lingwood et al. 2015). Domestic dogs appear able to acquire both allocentric and egocentric navigational skills, although they appear sensitive to an age-related decline in new task acquisition (Christie et al. 2005).

## Navigation to Objects by the Domestic Dog

Several activities and disciplines that the domestic dog partakes in are dependent upon an ability to navigate to specific objects. Retrieving specific objects is a typical task expected of many dogs, either for functional, working purposes (such as working gun dogs retrieving shot game) or for

exercise, pleasure, and competitive disciplines involving interactions between the dog and handler, such as “flyball” and competitive obedience. Activities and competitive disciplines that the domestic dog takes part in also include successful direction to and navigation around (and over) specific objects and visual targets, such as jumps in dog agility and send-away targets in obedience.

Catching airborne objects is a common activity that promotes the human-dog dyad in a playful fashion and has also developed into a competitive discipline that involves specific athletic moves by both dog and handler, culminating in the dog catching and retrieving a frisbee. Dogs appear to be highly successful in their ability to catch moving objects from the air, even when the objects are traveling at speed and with changing directions. Indeed, dogs seem to demonstrate “object permanence” in their ability to form and hold a mental representation of an object that has temporarily disappeared from vision. Dogs have been shown to demonstrate object permanence in studies that hid objects, and dogs were able to recover them after a period of time. There appears to be an ability to link specific environmental cues with the object, allowing a memory to be formed. This ability to navigate to an object is also critical for many working breeds of domestic dogs that undertake tasks related to object locating and retrieval in some cases. More generally, object permanence will likely support wild canids in their ability to detect, locate, and successfully hunt prey species during a chase.

Linked to the cognitive memory skill of object permanence is the ability to “object follow” in the case of moving objects. The ability of dogs to object follow and then navigate to that object is observed in their ability to successfully catch an airborne object. In this case, it appears that dogs utilize similar viewer-based navigational strategies to human baseball players and aircraft pilots, suggesting a common interception mechanism for moving targets in three dimensions (Shaffer et al. 2004). By examining how dogs caught an airborne frisbee, dogs appeared to maintain a linear optical trajectory (LOT) with an optical speed constancy until the object either changed direction or was intercepted. Where the object changed direction, study dogs simply established

a new LOT and optical speed (Shaffer et al. 2004). This is also in accordance with findings of predator species as diverse as bats and dragonflies for prey interception, where a consistent optical angle is maintained between predator and prey until a successful hunt conclusion (Simmons et al. 1979; Olberg et al. 2000).

## Conclusion

The ability of an animal to successfully navigate in time and space is critical for survival. Navigation permits directional movement in the pursuit of essential biological resources such as water, food, habitat, territory, and reproductive opportunities. While a wide array of techniques and biological adaptations are identified across the animal kingdom to support navigational abilities, in common with many other species, canine navigation appears to comprise a range of different strategies, with an opportunistic adoption of the most suitable strategy (or combination of strategies) in a given time and space. On this basis, identifying a single mechanism responsible for canine navigation is unlikely, and rather an acknowledgment of an integrated navigation system is pragmatic in the understanding of how canid species successfully negotiate location orientation and subsequent directional movement. A combination of innate, learned, and experiential behaviors with specific sensory skills based on visual, auditory, olfactory, geomagnetic, circadian, and other location identification abilities, in addition to local environmental conditions, helps to assist canine wayfinding and navigation, whether to a specific location, resource, or other object.

## Cannibalism

Carey Fitzgerald  
Oregon Institute of Technology, Klamath Falls,  
OR, USA

## Synonyms

[Anthropophagy \(in humans\)](#)

## Definition

The practice of consuming the body – such as organs or flesh – of one’s own species.

## Introduction

Cannibalism is a widespread phenomenon in the animal kingdom. While eating the members of one’s fellow species may seem evolutionarily counterintuitive, cannibalism provides many survival advantages to a wide range of animal species – including personal nourishment and increased reproductive benefits. This entry

discusses some theories regarding why cannibalism exists in nature, the evolutionary advantages that cannibalism provides, and the various animal species that engage in cannibalism.

## Cannibalizing Mates

Multiple theories regarding precopulatory cannibalism (consuming one’s sexual partner during courtship) have been posited. One theory – the *adaptive foraging hypothesis* – states that females of some species may assess and compare the reproductive and nutritional value of potential male mates (Barry et al. 2008). Malnourished females are more likely to cannibalize their potential mate and forego the reproductive opportunity out of their need for nutrition (Andrade 1998). Support for this theory has been discovered in various insects and arachnids, including praying mantises (Prokop and Vaclav 2008), and many different types of spiders (Andrade 1998; Johnson et al. 2011; Persons and Uetz 2005). Some evidence suggests this may also affect male sexual behavior. For example, male black widow spiders are more likely to pursue female mates that are satiated (Johnson et al. 2011). While cannibalizing a potential male mate eliminates a reproductive opportunity, the nutritional benefits may outweigh the costs. For example, cannibalism in female praying mantises is associated with increases in female fecundity (Barry et al. 2008).

Some researchers have proposed a controversial theory regarding precopulatory cannibalism known as the *aggressive spillover hypothesis*. Proponents of this theory state that cannibalizing one’s mate is a by-product of aggressive female foraging behavior; however, this theory has received significant criticism (Kralj-Fisher et al. 2013).

## Cannibalizing Offspring

Cannibalizing one’s own offspring may also provide survival advantages to the mother and other offspring in the litter. Consuming unhealthy and/or weaker offspring (i.e., offspring that have a low probability of survival) decreases competition for food among the surviving offspring.

Similarly, cannibalism in some snake species provides multiple benefits for the mother. Colombian rainbow boas will consume their non-viable eggs and offspring, which provides them with significant nourishment for post-reproductive physical recovery, rapidly increasing their constricting ability, which allows for more effective post-copulatory predation (Lourdais et al. 2005).

Some researchers have also proposed that consuming some of one's own offspring may help prevent the spread of disease, effectively maximizing reproductive output by sacrificing a small sum. Cannibalizing an infected offspring directly kills the parasites and reduces the number of possible hosts for the parasites (Van Allen et al. 2017). Thus, consuming the unhealthy offspring can protect the rest of the litter from infection, thus increasing their likelihood of survival. This is a rather controversial theory because many scholars believe cannibalism enhances the spread of disease within a species. However, mathematical models illustrate that disease transmission by cannibalism is very unlikely (Rudolf and Antonovics 2007; Van Allen et al. 2017). This is due to the fact that shared consumption of victims among members of one's species is necessary for significant disease transmission to occur, but shared cannibalism is rare (Rudolf and Antonovics 2007).

## Conclusion

Cannibalism is a common occurrence among many different species. While this entry focused largely on insects, arachnids, and reptiles, it is important to note that cannibalism has been well-documented in numerous mammals – including primates – as well. For example, chimpanzees have been known to cannibalize chimpanzees from other communities (Watts and Mitani 2000). This form of cannibalism occurs after the chimpanzees have killed their conspecific for territorial or intrasexually competitive reasons. Once the attacker's territory and/or mate is secure, the victim's carcass then provides nourishment. Cannibalism often provides a wide range of evolutionary advantages to members of one's species including nourishment, decreased competition for resources, and disease prevention.

## Canopy

Abhishek Singh

Department of Botany, Banaras Hindu University, Varanasi, India

## Definition

Canopy is the crown of any type of vegetation including leaves, branches, twigs, and the flora and fauna residing in it along with their microclimate (environment).

## Introduction

The term canopy was first developed during the study of tropical rain forest. However, several other vegetation such as kelp forests, sea grasses, gardens, crop fields, etc. also support canopy. Canopy is an important part of the vegetation especially in forest. It consists of uppermost part of any vegetation along with plants, animals, microbes, and their surrounding environment (Russell 2017).

The forest canopy is most diverse and influencing among the above canopies. Canopy biology is an emerging branch of forest science, which incorporates the study of tree crown and their inhabitants and the interactions among them. The forest canopy is a structurally complex subsystem of forest and which plays a major role in forest ecosystem. The growth of individual tree crown is dependent on the surrounding tree species and their environment. The plants in a natural ecosystem are of varied ages, shapes, and sizes. There is fierce competition among the plants for getting the space and sunlight. This can lead to changes in the individual plants in the canopy without much changing in the functioning of canopy. The functioning of canopy can be accessed in terms of their cumulative response toward the environmental factors. The canopies in natural forest ecosystem are multilayered; the upper layers have greater influence on lower layers of canopy. The upper canopy layers receive maximum sunlight compared to lower canopy layers (Russell 2017).

The fauna inhabiting the canopy are the integral part of the canopy and help in maintaining its structure and function. Other vegetation such as epiphytes, woody and non-woody climbers, parasitic plants, etc. are also important components of canopy. Thus, the canopy is the whole sum of associated flora, fauna, and the surrounding environment.

the main tree trunk. However, the tree crown of different tree species varied greatly in shape and sizes depending on the type of tree. Similarly, the canopy structure of different forest type depends on the type of trees present in the forest. It varies from temperate deciduous spruce forest to temperate evergreen pine forest, from tropical dry deciduous to tropical rain forest. The canopy structure also depends upon distribution of tree species in the forest. The canopy may be stratified into one to three regular canopy strata, with individual emergent plants and understory continuous layer of smaller trees.

The fauna inhabiting the canopy use it for browsing, feeding, nesting, mating, and resting. The animals live in the canopy are varied according to the canopy type, e.g., the fauna inhabiting the temperate forests are different from tropical forests. The species richness is highest in tropical forest canopies as they provide a wide array of niche due to their climatic conditions.

The main function of canopy is exchange of gases from the atmosphere mainly in the form of carbon dioxide, oxygen, and water vapor through photosynthesis and transpiration. The forest canopies generate microclimates by mitigating and equilibrating the disparity in climatic conditions, generating the gradient of mean PAR (photosynthetically active radiation) and changes in temperature and relative humidity. The forest canopies also affect the course of precipitation by trapping the rainfall and snow fall. The architecture and physiology of associated tree species and epiphytes in a forest canopy plays a crucial role in creating the microclimate which is further determined by the type of species, growth behaviors, and age distribution. Thus, the forest canopies play a crucial role in various biogeochemical cycles especially in water and carbon cycle. The microclimate generated by the forest canopies helps in sustaining a major part of earth biome.

## Architecture and Function of Canopy

A single tree crown is composed of the leaves, small twigs, and lateral branches emerging from

## Forest Canopies and Biodiversity

Forest canopies are biodiversity hotspots as they have one of the most species rich habitats on the

planet earth. Forest canopies especially rain forest canopies support a wide range plant, animal, and microbial species. Besides the associated tree species, the variety of epiphytic and climber plant species are the integral part of canopy (Nadkarni et al. 2013). However, plant species composition among the canopies varies according to the type of forests.

Invertebrates are the dominant fauna of the canopy; it comprises more than 90% of the species browsing the canopy. Vertebrates including temporary and permanent inhabitant (mammals, birds, reptiles, and amphibians) of canopy are merely 1% of total species inhabiting the canopy (Erwin et al. 2004; Robinson 1986). Arthropods are the dominant invertebrate fauna of forest canopies; Erwin (1995) found  $3.4 \times 10^{10}$  terrestrial arthropods per hectare in western part of central Amazonian rain forest. Insects, spiders, centipedes, millipedes, and mites are dominant among arthropods. Insects are the largest group of arthropods dwelling the canopies, several species of insects such as ants, beetles, butterflies, moths, and wasps. These insects including other arthropods are part of a complex food wave of canopies. They nearly present at all trophic levels of a food wave, from herbivorous beetles to predatory praying mantis. They occupy nearly about all possible niches in the canopy and perform crucial ecological functions such as pollination and seed dispersion, which are necessary to sustain a canopy.

Birds, lizards, and mammals are the dominant vertebrate fauna of the forest canopy. Food availability is the major governing factor for vertebrate fauna. Only tropical evergreen forests produce the food all over the year for herbivorous and insectivorous vertebrates. In deciduous and seasonal forests, the species which browse the canopy either browse on ground or hibernate during the scarce period (winter or dry). Nearly, all canopy dwelling mammals are found in evergreen tropical forests and are mostly scansorial. The timing and spatial distribution of flowering and fruiting plays a crucial role in controlling the behavior of these mammals. Anurans, lizards, and, up to some extent, snakes are the true canopy dwellers as they perform most of the

activities including foraging and mating in the canopy. Birds and bats are also one the most important elements of the canopy. The birds in the canopy are mostly insectivores, e.g., in the tropics nearly 50% birds are strictly insectivores, about 8% feed on both insect and nectar (Erwin and Zamorano 2017). These animals develop various special morphological adaptations in their limbs to browse the canopy, which provides firm grip on twigs, leaves, and scaly bark of the canopy trees. The ability to leap within canopy is the most common adaptation among neotropical mammals along with frogs and lizards as it conserves the energy and time to browse the canopy trees to find resources (Erwin 2013). However, the flying birds and bats are among the dominant vertebrate fauna of the tree canopy. Several other morphological adaptations help these organisms to camouflage in their environment which further enables them to avoid the predator and to capture the prey.

## Conclusion

The canopy is a broader term and it includes all the flora and fauna along with the associated microclimate. The interactions between canopy organisms and their surrounding environment have greater impact on the earth's climate. Canopies are the engines of the earth that drive the major biogeochemical cycles of carbon and water through photosynthesis and transpiration. The canopy harbors a great amount of species diversity of various plants and animals. The complex interaction among these organisms leads to the development of complex food waves. Various types of invertebrates and vertebrate fauna including spiders, insects, birds, frogs, reptiles, and mammals browse the canopy. The canopy animals develop several types of morphological and biochemical adaptations which enable them to efficiently utilize the resources present in the canopy. Thus, canopy is the one of the most influential and species-rich environment which governs the major biological and climatic aspects of the earth biome.

and scientific research and education, for companionship, for their labor, and for their own benefit (in particular sheltering and treating lost and sick animals). Many of these animals have been domesticated, and this domestication process raises ethical questions of its own, but here we will focus on wild animals in zoos and the question of under what circumstances it is morally justified to keep them in captivity.

Animal ethicists have put the interests of individual animals on the map and have argued that the interests of sentient animals and humans should receive equal consideration in like circumstances (Singer 1975) or that we should respect the rights of animals not to be unnecessarily harmed by us (Regan 1983). This translates into a rejection of the use of animals for purposes such as recreation, entertainment, education, or generating a profit. For this reason, animal ethicists are generally not supportive of keeping animals in zoos. As they focus on individual animals, the argument that zoos might be instrumental in the conservation of endangered species does not convince them. After all, animal ethicists generally hold that individual animals are the sole locus of moral concern, as they alone have experiential well-being, while collectives such as species or ecosystems are human-constructed categories that have no independent moral standing (Palmer 2009). Regan (1995), for example, argues that animals can only be kept in zoos if this aids the protection of the particular animals in question. An example could be the sheltering of former circus bears that can no longer be returned to the wild. For utilitarians, conservation in zoos in theory could contribute to the interest of a group of animals, but in practice they tend to bring about too many welfare problems to be justified. In other words, the future survival of a species does in their eyes not trump the interests of currently existing individual animals; we cannot make a trade-off between the interests of individuals and their group. Others, on the other hand, have argued that both the interests of individual animals *and* the interests of their population or species should matter to us and that we should embrace a

Research, Wageningen, The Netherlands

## Introduction

Animals are kept in captivity for many different purposes, such as recreation or entertainment, for their products, for medical experimentation

bifocal view on animal welfare and species conservation (Keulartz 2015), or what Ramp and Bekoff (2015) have termed “compassionate conservation.”

In this contribution, we first discuss inherent objections to keeping wild animals in captivity. We will in particular discuss the question of whether animals have an intrinsic interest in freedom. Next, we will address moral justifications for and objections to keeping animals in captivity. In the second part of the chapter, we discuss the questions of under what circumstances harm to the interests of individual animals is acceptable for species conservation and what it would imply for the organization of zoos were they to take their conservation role seriously.

## Is Animal Captivity Inherently Wrong?

From the animal rights spectrum of animal ethics, it has been argued that keeping animals in captivity is inherently morally wrong, because it commodifies them and turns them into property (Francione 2010) or fails to respect their inherent value, as it treats them solely a means to our ends (Regan 1995). Even though animals might in practice be treated as though they were property or lacking in inherent value, it is not entirely clear why this would be a consequence of captivity by definition. After all, animals kept in wildlife refuges or as pets are not entirely free either, but this does not mean they are used as solely a means to our ends. Moreover, regarding animals as property from a legal perspective – as is common in many countries – does not mean they are commodified in a moral sense. Even though companion animals are deprived of certain freedoms, they are not commonly regarded as property, with which we can do whatever we want, but rather as friends or even family members.

Nevertheless, it has been argued that animals have an interest in freedom as such (p.e. Pluhar 1995; Rollin 1992). Cochrane (2009) disputes this; he makes a distinction between an instrumental and an intrinsic interest in freedom. Freedom is an instrumental interest for animals in so far as it facilitates “other goods, such as the avoidance of

suffering” (Cochrane 2009, 661). However, it is – at least theoretically – possible to deprive an animal of freedom without depriving it of these other goods. Most human beings, on the other hand, do have an intrinsic interest in freedom, or liberty, because they have a stake in being free from control and being the author of their own lives. According to Cochrane, they have this interest due to the fact that they are autonomous agents who have the “capacity to frame, revise and pursue their own conception of the good” (idem, 665). He argues that most animals (save perhaps primates and cetaceans) do not possess the relevant type of autonomy characteristic of human beings, which is dependent on the capacity to have “second order” desires, or in other words being able to reflect on one’s desires. (Indeed, lawyers and scholars from the Nonhuman Rights Project have argued that chimpanzees Leo and Hercules, due to their sophisticated mental capacities, should be accorded the status of legal persons. This would imply that they cannot be deprived of freedom. See <https://www.nonhumanrights.org/?s=hercules>.) The interest humans have in freedom stretches beyond a purely instrumental interest in wellbeing. Even if they would be perfectly happy under conditions of captivity (for example in slavery), taking away the possibility of being the author of their own lives would render captivity in itself wrong for them. But do animals not possess the required type of autonomy to give them an interest in being the author of their own lives? It could be argued that we should understand autonomy as a gradual notion, as is common, for example, in medical ethics. After all, a person in the first stages of dementia can still decide what she wants to have for dinner or what television program she wants to watch, but this person can no longer make important financial decisions. Could something similar count for animals? And would this mean that they have an intrinsic interest in liberty, albeit in a more limited sense?

It seems likely that animals have an interest in making certain decisions for themselves, such as what conspecifics to mate with, even though they may not be able to foresee the implications of larger decisions, for example, about their far

future. This would suggest that perhaps the distinction between instrumental and intrinsic interest is not as strict as Cochrane suggests. According to Gruen (2011), many animals are able to frame their own conception of the good life. She cites evidence that shows that many animals at least have concepts and she argues that many animals can devise their own plans in life. She argues that many animals pursue certain ends, shape their own lives, adapt to changing circumstances, make choices, and try to improve their environment, not only on their own but also by means of collective action (Gruen 2011, 150). The jury is still out on the question of whether this toned-down version of autonomy means that animals have an intrinsic interest in being free from captivity. Even though many examples exist of animals trying to escape captive situations (Hribal 2011), the question remains whether this should be interpreted as a simple fear- and flight response, or as an objection to captivity as such. We are inclined to think that many animals do have an intrinsic interest in liberty, but that this interest is not absolute. This entails that the interest in liberty could be trumped in certain cases, provided that the animal is treated well, for example, when the animal in question is a member of an endangered species that can only be saved when bred in captivity or when its own native habitat is no longer suitable for survival.

### Justifications Versus Objections

Even if animals can be said to have an intrinsic interest in or right to liberty, this does not have to lead to an absolute obligation on the part of humans to liberate all animals. The interest would still have to be weighed against other interests (or the right could be trumped by other rights). Therefore, we also have to take a look at possible justifications that could be given for animal captivity and weigh these against animals' instrumental and intrinsic interests in liberty. Both humans and animals themselves could have an interest in captivity in zoos. Of course, humans benefit from the entertainment zoo animals provide, but zoos can also play a role in education and

scientific research. Animals in captivity – provided they are well cared for – enjoy shelter from the elements, protection from predators, medical care, and a steady food supply. It is at least not self-evident that a life in the wild is better for animals than a life in the zoo. For example, in the wild many animals die at a young age; this in fact is part of evolution.

On the other hand, many objections have been levelled at zoos. Of course, when wild animals are not able to live in their natural habitat and carry out their species-specific behavior, when they have less space to roam around and have their social structures disrupted (by not being able to select their own mates, for example), this will lead to animal welfare problems (Jamieson 1985). How these problems weigh up against the benefits experienced from zoos is dependent on the assessment of the gravity of the harm done to the animals vis-à-vis the seriousness of the human or animal interests involved. The outcome will differ from practice to practice.

It should be noted here that while this assessment definitely has an empirical component, its outcome also very much depends on the particular concept of animal welfare that is used. Animal welfare is not just a biological term; rather it is an evaluative term that combines biological knowledge and moral norms (Bovenkerk and Meijboom 2013). In general, three views on animal welfare can be distinguished: (1) the view that animal welfare is guaranteed when animals can cope with the conditions they find themselves in; (2) the view that it is guaranteed if the animals experience subjective well-being; and (3) the view that the extent to which an animal can carry out its natural or species-specific behavior is constitutive of its (Fraser 2003). In particular the last view on animal welfare has proven difficult to meet in zoos, due to limitations of space and budget, but also due to moral considerations. After all, feeding a predator live prey, while conducive to predator welfare, will lead to pain and distress on the part of the prey (and human zoo visitors). Also, if we consider that animals have a right to reproduce, what do we do with the resulting surplus animals (Kasperbauer 2016)? These animals may have to be killed and it is this practice of

“zoathanasia” that elicits a lot of criticism. (For example by Marc Bekoff. <https://www.psychologytoday.com/blog/animal-emotions/201208/zoathanasia-is-not-euthanasia-words-matter>) Being exposed to human visitors, especially when animals do not have a place to which they can withdraw, can lead to stress. In zoos stereotypical behavior, such as pacing, self-biting, and excessive self-grooming, are found, and these point to welfare problems according to all three views on animal welfare. Stress, boredom, and social isolation are the most common causes of these behaviors. (A study has shown, for example, that gorillas in zoos that are confronted with many visitors are more likely to show stereotypic behaviour – consisting of autogrooming, abnormal behaviour (such as teeth clenching, body rocking, and more banging on the separation barrier) taking less rest, and aggression towards other gorillas – than those who are confronted with low visitor density. This indicates that visitor density leads to stress in the animals. See Wells 2005, who also cites other studies with similar conclusions.) Loss of freedom and lack of control over an animal’s life can lead to what animal welfare scientists refer to as this animal’s “learned helplessness.” (The theory of learned helplessness was first put forward by psychologist Martin Seligman 1972, who showed that dogs that have been given electric shocks become so passive that they fail to avoid further adverse stimuli, even if there is an easy possibility of escape. They are in effect conditioned to believe that harm is inescapable.)

In sum, whether human and animal interests in zoos outweigh disadvantages in a particular practice of captivity is not a straightforward assessment, but will be open to discussion about how we weigh animal interests and what we mean by animal welfare in the first place, and will of course depend on the efforts made by a particular zoo to counter welfare problems. However, objections that go beyond welfare issues can also be levelled against zoos.

First of all, it could be argued that wild animals in zoos become less wild. One could even wonder to what extent we are still dealing with wild animals, in particular when animals were born in the zoo. This judgment, of course, would depend on

one’s definition of wildness (see Palmer 2016 for a discussion of different types of wildness). If we were to regard wildness as a gradual notion and animals less wild the more they are dependent on humans and the better they are adapted to humans, it would appear that many zoo animals score high on the factor of dependence and low on the factor of adaptation (Swart and Keulartz 2011). We can discern a tension here: on the one hand the animals will experience better welfare if they score high on both factors, but on the other hand, if they are in a breeding program and they will eventually be returned to the wild, it would be best if they scored low on both factors.

But why is wildness of zoo animals important? Similar to the interest in liberty that we discussed above, it could be argued that wildness can be either an intrinsic or an instrumental value. As an instrumental value, wildness can be important to animals because it implies freedom to roam about and carry out self-willed action (Palmer 2016). As an intrinsic value it refers more to a quality about the animals that human beings attach value to and that is quite hard to grasp: It refers to having come about independent from human action, inspiring awe for evolutionary processes, and being somehow in harmony with nature. Regardless of how one interprets wildness, it is a fact that many people visit the zoo to encounter wild animals, not domesticated ones, and the objection is that zoos are presenting visitors with an illusion.

A second criticism of zoos is that they do not live up to their claim that they perform a role in educating the public. First of all, research on the educative effect of zoos is inconclusive (Marino et al. 2010). Secondly, it could be questioned what watching wild animals in enclosures teaches people about the human-animal relation and what attitude towards animals it engenders. Does it adequately convey to children that animals such as bears when encountered in the wild, are actually dangerous? Does it inspire respect for animals or show that humans are superior to the animals on the other side of the glass that have been captured and tamed by us? In particular when wild animals are made to perform in zoos, doesn’t this interfere with their wild dignity (Gruen 2011;

Brando 2016)? Finally, can the supposed educational benefits of zoos not be acquired in a different way, such as watching nature documentaries or attending lectures (Jamieson 1985)?

All of the aforementioned considerations play a role when we have to weigh the arguments in favor and against keeping animals in zoos. So far, we have mainly looked at pros and cons regarding individual animals. Next, we will look more closely at the argument that zoos play an important role in species conservation.

### Captivity for Conservation?

Today, the animal world is under growing pressure, with the result that animals suffer massive losses of freedom of movement and of control over their own lives. In fact, we are in the midst of the so-called “sixth mass extinction.” Paleontologists speak of a mass extinction when the Earth loses more than three-quarters of its species. This has happened only five times in the past 540 million years, the last time 65 million years ago when dinosaurs disappeared from this planet. Experts estimate the current extinction rate at 100–1,000 times the normal rate between mass extinctions, the so-called “background extinction rate.”

However, to fully assess the current situation, one should not only consider the extinction of species but also the decline in numbers and sizes of populations. The 11th edition of the WWF *Living Planet Report* from 2016 shows that the population sizes of vertebrate species (mammals, birds, fishes, reptiles, and amphibians) have dropped by almost 60% in little more than 40 years and are likely to reach 67% by the end of the decade. Mainly due to habitat fragmentation and habitat loss, an increasing number of wildlife populations are declining and teetering on the brink of extinction. When we consider that population extinctions are a prelude to species extinctions, it becomes clear that “the window for effective action is very short, probably two or three decades at most” (Ceballos et al. 2017, 7).

As a response to this critical situation, and in order to find a new justification for keeping

animals, zoos began to turn their attention to the conservation of endangered species and wildlife in the 1970s and 1980s. *Captivity for Conservation* became a crucial slogan for the modern zoo. A major milestone in this development was the Convention on Biodiversity which was signed at the Earth Summit in Rio de Janeiro in 1992. In the wake of the Earth Summit, the first *World Zoo Conservation Strategy* was launched in 1993. Its conclusion explicitly stated that at a time when species, habitats, and ecosystems worldwide are threatened with extinction, modern zoos must commit to the conservation of species and wildlife.

Another important milestone concerns the so-called One Plan Approach that was officially proposed to the IUCN World Conservation Congress in 2012. This approach is intended to address the problem that both captive and wild populations are often not viable on their own. Like zoo populations, wild populations increasingly suffer from the lack of sufficient space to maintain self-sustaining populations due to the ongoing reduction and fragmentation of their habitats. To tackle this problem, the One Plan Approach promotes the interactive exchange of animals between wild and captive populations. With animals moving in both directions, the stability and sustainability of wild and captive populations can be greatly enhanced. Captive populations can be used for restocking in areas with declining populations or for reintroduction in areas where populations have gone extinct. And genetic founders from wild populations can boost the demographic and genetic viability of captive populations (Byers et al. 2013).

### Towards a Bifocal View on Zoo Animals

With the One Plan Approach, the distinction between in situ (on site) and ex situ (off-site) conservation is becoming increasingly blurred. The collapse of the fences between the “wild” and the “walled” and the integration of zoo-based tools and techniques in species conservation has led to manifold conflicts between animal protectionists and wildlife conservationists

(Minteer and Collins 2013). Whereas animal protectionists reject the whole idea of “captivity for conservation,” conservationists generally perceive animal welfare and animal rights concerns as obstacles to species conservation. Both parties adhere to opposing ethical frameworks: the individualistic framework of mainstream animal ethics in which species are of little or no moral relevance, and the holistic framework of environmental ethics that tends to make the rights and welfare of individual animals subordinate to the interests of the greater whole of which they are part, such as species or ecosystems.

Animal ethicists and environmental ethicists usually not only differ with regard to the locus of moral concern – individual organisms or greater wholes – they also tend to use different species concepts (Sandler 2012, 4). Animal ethicists have generally adopted a *conventionalist* species concept; they see a species merely as a category or class with arbitrarily drawn boundary lines that may serve as a convenient mapping device for theoretical purposes only (Jamieson 1995, 61). Environmental ethicists, on the other hand, generally hold a *realistic* species concept. Holmes Rolston, for instance, argues that a species is a real historical entity, a “dynamic historical lineage” that can persist as a discrete, vital pattern over time (Rolston 1988, 151).

In order to put an end to the seemingly intractable controversies between animal protectionists and wildlife managers and to integrate their conflicting ethical frameworks, one will have to develop a bifocal view in which zoo animals are simultaneously perceived as individuals in need of specific care and as members of a species in need of protection. It can be argued that animal welfare and wildlife conservation are two sides of the same coin, “by showing that the integrity of habitats and the populations they contain are inextricably linked to the welfare of the individual animals that constitute those populations and occupy those habitats” (Paquet and Darimont 2010, 179). If animal welfare concerns are ignored, wildlife conservation policies are likely to fail, and vice versa (Fraser 2010, 123).

From a bifocal view on zoo animals as individuals and species members, zoos can pursue an

ethically defensible policy only if they succeed in achieving a fair balance between animal welfare concerns and species conservation commitments. The prospects for the zoo to achieve such a balance are promising. Since early twenty-first century, zoos have made serious and sustained efforts to ensure and enhance animal welfare. At the same time, the zoo’s contribution to species conservation has also improved considerably.

### Overcoming Welfare Problems Caused by Space Shortage

Many of the welfare problems of zoo animals are produced by spatial limitations. Due to the lack of sufficient space, an animal’s freedom of movement and its options for the expression and development of species-specific behaviors are severely restricted – the enclosures are simply too small. Furthermore, to the extent that conservation breeding programs are successful, the animal populations will almost certainly exceed the zoo’s carrying capacity. This situation creates the so-called “surplus animal problem.” Traditional methods to solve this problem include culling the surplus animals or selling them to dealers, where they often end up in substandard facilities (Carter and Kagan 2010).

To address the welfare problems caused by space limits, zoos have a number of options. They can reduce the number of species they maintain that are not threatened and specialize in species that are. “Specialization is key to every successful threatened species propagation program” (Conway 2011, 5). In addition to specialization, zoos can increase and improve regional and global cooperation. In order to be demographically and genetically viable, the size of captive populations managed in isolation generally needs to be very large. The problem of low zoo animal numbers can be addressed by collaborative management and the exchange of animals among zoos.

Another strategy to combat the problem of limited space is the shift away from large charismatic mammals – such as elephants and giraffes – towards smaller species, particularly amphibians,

invertebrates, and some species of fish, which occupy less space, are relatively inexpensive to keep, generally experience less welfare problems in captivity, have a high birth rate, and are easy to reintroduce, while maintaining their social structures. Several initiatives have already been launched on this front, not least the Amphibian Conservation Action Plan, a partnership involving the World Association of Zoos and Aquariums (WAZA) (Gewin 2008).

Yet another, recent and very promising, strategy to overcome the problem of space shortage concerns the improvement of enclosure design by creating walkways between enclosures that allow animals greater freedom of movement. Building a network of trails, in particular top tree trails, gives animals the opportunity to rotate between various interconnected display and off-display areas, such as dens, basking sites, and foraging areas. Animals may spend mornings in one area and afternoons in another (Coe 2004). An additional benefit might be the reduction of stress induced by high visitor densities.

### **Improving Animal Welfare by Environmental Enrichment**

In recent years, zoo management has undergone a real transformation to the benefit of animal welfare due to the introduction of “environmental enrichment” programs (Kleiman 2010, xi). The main goals of enrichment are to reduce stress, to enable animals to show species-specific behavior, and to increase their capacities to survive and reproduce if released into the wild.

A growing number of options for providing environmental enrichment have been developed recently: physical enrichment involves the introduction of “toys and treats” that induces play behavior and exploratory activities; occupational enrichment encourages exercise and training; feeding enrichment takes many forms, such as increasing the number of daily feeding sessions, making the feeding schedule less predictable, and making the food less easy to obtain; and sensory enrichment makes use of visual, auditory, and olfactory stimuli.

The perhaps most powerful and successful type of environmental enrichment is social enrichment, which provides animals the opportunity to interact with other animals, either conspecifics (same species) or contra-specifics (other species). Mixed-species exhibits are a good example of the latter. They provide an interactive and dynamic experience for the animals, visitors, and zoo staff. In mixed-species enclosures, activity levels are typically higher, with more play behaviors, and this generally has a positive effect on both the physical and the mental health of the animals. Moreover, interspecific interactions can contribute to successful reintroductions. Animals from mixed-species exhibits are more likely to cope with the complexity of their natural habitat after introduction. Even “negative” interspecific interactions, e.g., controlled nonlethal exposure to predators, may be beneficial in survival post-release (Veasey and Hammer 2010). In order to increase the success of breeding in captivity and reintroduction into wild habitats, pre-release training needs to be given. This will also (at least partially) help to overcome the problem, mentioned above, that zoo animals become less wild. Pre-release training is aimed at maintaining or developing the skills that may have been lost in captivity such as orientation and navigation, finding or building suitable nest sites, hunting and foraging behavior, and predator avoidance (McPhee and Carlstead 2010).

### **Broadening the Zoo’s Conservation Role**

Since the early years of this century, zoos have not only succeeded in substantially improving animal welfare, they have also made real progress regarding their contribution to species conservation. The new *World Zoo and Aquarium Conservation Strategy* of 2005 outlines a much broader conservationist role for zoos than the first *World Zoo Conservation Strategy* of 1993, including research, training, education, awareness campaigns, and direct support for in situ projects. In the latest strategy, the primary mission of zoos is to integrate all these elements with their efforts to protect endangered species and conserve healthy

ecosystems (Mace et al., 2007; Bowkett, 2008; Lees and Wilcken 2009). Insofar as captive-breeding for reintroduction is considered necessary and appropriate, it should be accomplished as part of such a larger, integrated, holistic program (Hutchins 2003, 18).

The simplest way for zoos to assist in situ conservation is through financing and fundraising. The amount spent on conservation by zoos is significant. Members of the WAZA are the third largest financial supporter of species conservation in their natural habitats (providing US\$350 million/year), after the Nature Conservancy and the World Wildlife Fund (Conde et al. 2011).

Another important way for zoos to contribute to in situ conservation is through research and training. Exporting expertise is at least as important as repatriating animals (Stanley Price and Fa 2007, 169). As natural habitats continue to be damaged and destroyed at the current pace, the tools and technologies developed by zoos are becoming increasingly relevant for in situ conservation. Research within zoos, such as behavior studies, genetics, reproduction, and nutrition, are increasingly relevant for research in the wild. Moreover, zoos can support in situ conservation by providing technical skills and by training conservation scientists (Zimmerman 2010, 282).

But the perhaps most important contribution of zoos to in situ conservation comes from education, awareness, and advocacy. It is realized by now that the 700 million people that annually visit zoos are significant conservation assets, at least as valuable as the zoos' animals. Only recently have zoo professionals begun to objectively assess their educational impact on visitor conservation knowledge, awareness, and behavior, in order to learn and improve their competence as agents of change. There still remains much to be done in order to achieve this educational impact.

To enhance the effectiveness of zoo visits to inspire conservation awareness and action, zoo professionals have shifted the focus from cognitive learning to affective learning. In addition, they have recognized that behavioral change on a measurable scale is only feasible if zoos succeed in encouraging accessible actions that people can

take to support wildlife. A good case in point is Monterey Bay Aquarium that hands out the Seafood Watch Pocket Guide to its visitors. As it turned out, this guide significantly changes the seafood-buying habits of 80% of visitors who take one home (Routman et al. 2010).

## Conclusion

In this chapter, we have argued that the distinction between intrinsic and instrumental interest in freedom for animals is not as strict as Alistair Cochrane suggests. If we conceive of autonomy as a gradual notion, it appears that animals have an intrinsic interest in liberty, albeit a more limited one than is the case for most human beings. This entails that the interest in liberty could be trumped in certain cases – provided that the animal is treated well – for example, when the animal in question is a member of an endangered species that can only be saved when bred in captivity or when its own native habitat is no longer suitable for survival.

In order to make a sound moral judgment about animal captivity, we have to take a look at possible justifications that could be given for animal captivity and weigh these against animals' instrumental and intrinsic interests in liberty. We have discussed the objection that zoos lead to animal welfare problems due to limitations of space, budget, and the inability to carry out species specific behavior. Objections beyond welfare also have to be taken into consideration: zoo animals become less wild and the educative potential of zoos can be questioned. In the end, a judgment will have to be made taking into account the specific context. Some zoos are better able to meet the stated objections than others, and there are certain criteria that zoos will have to meet to be morally acceptable: they should specialize in threatened species, focus on smaller animals, innovate their design to overcome space problems, provide enrichment, practice pre-release training, and broaden their conservation and education role.

On the basis of present trends – the development of animal enrichment programs on the one hand and the improvement of the contribution to

in situ conservation on the other – one can conclude with some confidence that the prospects for zoos to achieve an ethically acceptable balance between animal welfare concerns and species conservation commitments are indeed promising. However, the zoo community still needs to deliver on this promise. Today there are between 7,000 and 10,000 zoos worldwide, many of which will not meet the high standards of the 1,600 zoos which are members of WAZA or of its affiliated associations at national and regional levels. And even among the members of these accredited zoo associations, the implementation of high standards and good practices leaves much to be desired. The direction is clear, but there is still a long way to go.

## Cardinality

Irene M. Pepperberg  
Department of Psychology, Harvard University,  
Cambridge, MA, USA

## Synonyms

[Exact number](#)

## Definition

“The number of elements in a set or group.”

## Introduction

Cardinality can be defined in multiple ways, depending on the theoretical stance that is being taken (e.g., for some theoreticians, it can involve the number of points that make up a geometric line). For the purposes of research on the development of number concepts in young children and nonhuman animals, it is generally defined as the symbolic representation of the exact number of items in a set. Thus, for English speakers, given the set “apple, apple, apple, apple, apple” and the query “How many?”, the cardinality of the set is represented by “five.” “Apple” can be replaced with anything, from a subatomic particle to a planet, to sounds or actions, and the response to “How many?” will be the same, because

cardinality is not based on mass, contour, density, or any other irrelevant attribute but only specific numerical quantity (e.g., Mix et al. 2002).

### Cardinality in Relation to Other Numerical Concepts

A simpler, implicit understanding of cardinality also can exist, as when young children respond to the equivalence of very small sets (1–3 items), but such behavior is not the same as understanding explicit cardinality (see discussion in Carey 2009). Here children are creating working-memory models of the sets and relating the sets on the basis of various associations (e.g., 1:1 matches), but do not need to use symbolic representation of number.

Use of numerical labels for cardinality is also very different from use of such labels in an analog system. The analog number system, or ANS, allows *approximations* to cardinality, proportional to the number of objects in the set – that is, based on Weber’s Law (see Dehaene 2009). Thus, if subjects lacking symbolic representation of number are asked in some manner to distinguish sets of more than about three items, their responses form a curve around the correct cardinality, with the broadness of the curve becoming proportionally fatter as the number to be determined increases (e.g., Platt and Johnston 1971). The ANS is evolutionarily ancient, and just about every animal studied is capable of its use, from bees and salamanders to fish, many species of birds and various nonhuman primates (review in Carey 2009).

### Cardinality and Counting

Cardinality is inherent in understanding “counting principles” and the “successor function.” For children to acquire counting principles (CP), they must have a symbolic ordinal numerical list, in which each symbol represents the exact cardinal value for every numeral in the list. CP, according to Gallistel and Gelman (1992), state: numerals must be applied in order to items in a set to be

enumerated, must be applied in 1–1 correspondence, and the last numeral in a count represents a set’s cardinal value. To understand cardinality, children must also understand the successor function, which means that they recognize that each number in the list represents exactly one more item than the number before it (see also Fuson 1988). No evidence exists for mental representations of exact cardinal values of sets greater than four by adult humans in cultures lacking verbal numerals or a tally system (Frank et al. 2008; Gordon 2004; Pica and Lecompte 2008), deaf adults lacking natural language input (Spaepen et al. 2011), preverbal infants (e.g., Feigenson et al. 2004), or most nonhumans (except those taught explicit symbolic representations, see below; see Pepperberg and Carey 2012).

CP acquisition is difficult and children take several years to acquire the requisite numerical skills, which allow for cardinal understanding of all numbers (see Carey 2009; Fuson 1988; reviewed in Pepperberg and Carey 2012). Two-year old English learners can produce a count list, but some use idiosyncratic orders of numerical symbols (e.g., “one, two, six. . .”; see Gelman and Gallistel 1978). They assign exact cardinal meaning only to “one”; other numerals mean “some” or “plural”. Some nine months later, they learn “two”; other numerals are “more than two”. A few months later they master “three”, and a bit later “four”; by about this point in their development (and for many children even earlier) they also produce a standard count list. Only at this stage (generally close to four years of age), however, are children able to induce the CP: They make the connection between the count list and the quantities, infer that each successive numeral in the count list is exactly one more than its predecessor, and can thus induce the cardinality of larger numbers from their ordinal position on the count list.

### Cardinality and Nonhuman Subjects

Only three nonhumans have acquired symbolic representation of number – and thus likely cardinality. Two were chimpanzees (*Pan troglodytes*),

Matsuzawa's Ai and Boysen's Sheba; the third was a Grey parrot (*Psittacus erithacus*), Pepperberg's Alex. Notably, Ai could respond correctly only up to and including the number nine; Sheba and Alex were successful only up to and including eight. All three subjects could both comprehend and produce numerical symbols within this range with equivalent facility. Production, which came first for all subjects, involved seeing a collection of items and using a verbal label (either an Arabic numeral or a numerical vocalization) to identify the quantity. Comprehension involved seeing an Arabic numeral or hearing a vocal numerical label and picking out the corresponding collection of objects. Such comprehension-production equivalence is critical for claiming that the symbols comprise a true representational system (Savage-Rumbaugh 1986) and, thus, that these subjects understood cardinality. Sheba and Ai, however, did not immediately transfer their numerical knowledge to comprehension tasks and had to be trained after succeeding on production (Boysen 1993; Biro and Matsuzawa 2001); in contrast, comprehension emerged without training for Alex (Pepperberg and Gordon 2005). Interestingly, each of these subjects took many years beyond those needed for children to reach the same stage of numerical competence (Biro and Matsuzawa 2001; Boysen 1993; Boysen and Berntson 1989; Boysen et al. 1993; Matsuzawa 1985, 2009; Matsuzawa et al. 1991; Pepperberg 1987, 1994, 2006; Pepperberg and Carey 2012; Pepperberg and Gordon 2005; Tomonaga et al. 1993).

Of note, too is that neither ape engaged in the bootstrapping process that underlies children's mastery of the counting principles and, at some level, understanding of cardinality; that is, being able to infer the cardinality of novel numbers from their ordinal position on the number line without training (e.g., Carey 2009). Only Alex succeeded at that task (for a discussion of possible reasons for his success, see Pepperberg and Carey 2012). Alex's exact representation of number was also tested in ways not tested with other nonhumans (Pepperberg and Carey 2012): Given trials including differently colored sets of nine or ten items at the same time as sets of seven and eight (e.g., a

tray consisting of many pieces of wood – seven blue, eight green, and nine orange, all randomly arranged) and asked "What color seven?" or "What color eight?", Alex never once gave the color of the 9- or 10-item set, despite the fact that these sets are approximately eight. Such responses also show that he did not simply look for the largest set to label with his largest actual cardinal numeral, or use an ANS. If given trials with differently colored sets in which the targeted set was absent (e.g., "What color six?" when no set of six existed), he did not respond with the label indicating a set close in number but responded with the label "none", demonstrating that he knew that the exact set was missing.

Cardinality is also required for performing mathematical manipulations. Both Sheba and Alex could perform addition for small sets; that is, they could combine the cardinality of two or more sets each represented by an Arabic numeral and then represent this total by the appropriate Arabic numeral (Boysen and Berntson 1989; Pepperberg 2012). In both studies, the nonhumans were asked about the sums when the addends were no longer visible; that is, they had to remember the separate addends, perform the summation, and then either touch (Sheba) or produce vocally (Alex) the symbol that represented the exact total quantity. Number symbols were thus abstract representations of real-world sets. Importantly, neither Sheba nor Alex had had specific training prior to their testing, and neither was making judgments based on relative quantity between or among sets, but rather they were exactly mapping their answers to the cardinal value of the total number represented by the Arabic numerals. Their results were not subject to issues such as Weber's Law (i.e., they did not use an ANS). Sheba could sum two sets representing combinations of the Arabic 0, 1, 2, 3, 4 to a total of four at a statistically significant level. Alex could sum two sets representing various combinations of the Arabic 1, 2, 3, 4, 5 and sometimes an empty cup (zero) to a total of eight, and three sets of various combinations of the Arabic 1, 2, 3 and sometimes one or two empty cups to a total of six at a statistically significant level. He died before all possible combinations could be presented.

Thus, acquiring some level of understanding of cardinality does not seem to be a uniquely human trait. It does, however, appear to be one that requires considerable processing power and instruction, more so for nonhumans than for humans.

## Caretaker Effect

Ori Pomerantz  
California National Primate Research Center,  
Davis, CA, USA

## Synonyms

[Caregiver](#); [Care staff](#)

Caretaker effect refers to any direct (e.g., feeding) and/or indirect (e.g., noise levels that result from husbandry activities) influence that staff exert upon the animals under their care. Caretakers are involved in most aspects of the lives of the animals for which they are responsible and therefore play a significant role in determining their quality of lives and psychological welfare levels. Wild animals that live in their natural habitats constantly engage in decision-making and employ various responses to the many challenges that they meet daily. This ability ensures their survival and is an inherent part of their adaptableness. However, the ability of animals that are housed in captive settings such as biomedical facilities, agricultural farms, and zoos to demonstrate such flexibility is often restrained. Thus, for example,

the ability to react to the motivation to flee in a response to a threatening stimulus, or to emigrate from the natal group upon reaching puberty in order to search for unfamiliar mates in other groups is greatly curtailed due to decisions made by humans (In this case, confine the animals in cages). Decreased ability to control the environment and to successfully cope with its challenges by producing appropriate reactions has been suggested to be detrimental to the welfare of the animals (Dawkins 1990; Hill and Broom 2009). Furthermore, humans, particularly caretakers, are in charge of many decisions that animals would otherwise make on their own. For instance, caretakers are responsible for feeding the animals with certain foodstuffs at particular times and in a specific fashion (e.g., chopped vs. whole), and are intimately involved in the determination of the animals' social environment (e.g., which animals will be housed in the same room). Additional factors such as the temperature and humidity, veterinary care, and in some cases even the end of life are all in the hands of the humans who interact with the animals every day, namely the animals' care takers. Clearly, the caretaker effect on the lives of the animals is quite dramatic. While many of the caretaker activities are required for the proper functioning of the facility and are mandated by regulatory guidelines, the manner in which they are executed is to a large extent in their hands. Caretaker-animal relationships are developed during continuous close-up interactions, and many studies have demonstrated that different approaches for care yield different types of relationships and ultimately different results. Among farm animals, for instance, negative interactions which involve rough handling induce high levels of fear (Brajon et al. 2015). Similarly, laboratory-housed nonhuman primates are more fearful and aggressive toward caretakers with whom they have had prior negative experiences. Conversely, while some routine husbandry procedures may be perceived as threatening, laboratory-housed animals who maintained positive relationships with their caretakers are less likely to be disturbed by these activities (Waitt et al. 2002). In some cases, caretakers may even

play a surrogate social role and thus enable animals to express species typical behaviors, which otherwise would be prohibited and/or expressed inappropriately. A more structured form of positive interactions is the use of positive reinforcement training, in which the trainer (who is often the caretaker) gradually shapes a desired behavior of the animal with the use of rewards. The use of this technique not only creates a platform for the expression of positive behaviors towards the animals, but also offers the animals with means to predict events in their environment and better control it (Claxton 2011). Generally, positive interactions with caretakers have been shown to contribute to the wellbeing of captive animals as evident in both behavioral (e.g., more affiliative and less stress-related behaviors) and physiological measures (e.g., higher levels of oxytocin, weight gain, and lower blood pressure). Caretakers are likely to benefit from establishing such positive relationship as well. Indeed, routinely engaging in positive interactions with animals facilitates their management, by, for example, gaining the animals' cooperation when shifting them between enclosures, and having the ability to provide some medical care without the necessity of restraint (Laule et al. 2003). Positive caretaker effects are additionally linked to increased productivity among farm animals. The recognition of the significant constructive effects that positive caretaker-animal interactions are likely to yield on the animals is additionally reflected in formal regulatory documents such as the United States Department of Agriculture Animal Welfare Act and Animal Welfare Regulations.

## Carnivora

Andrew J. Edelman

Department of Biology, University of West  
Georgia, Carrollton, GA, USA

## Synonyms

[The mammalian carnivore order](#)

## Definition

Carnivora is a mammalian order that includes bears, cats, dogs, seals, skunks, and weasels, among other species.

## Introduction

The mammalian order Carnivora encompasses 15 families and 286 species (Fig. 1) including humankind's longest domesticated companions, cats and dogs. It includes both terrestrial carnivores (fissipeds) and aquatic carnivores (pinnipeds). Although there is ongoing debate regarding its taxonomy, molecular and morphological evidence supports organizing Carnivora into two suborders: (1) Feliformia that includes the families Eupleridae (Malagasy carnivores), Felidae (cats), Herpestidae (mongooses), Hyaenidae (aardwolf and hyenas), Nandiniidae (African palm civet), and Viverridae (civets, genets, linsangs, and relatives) and (2) Caniformia that includes the families Ailuridae (red panda), Canidae (dogs, foxes, wolves, and relatives), Mephitidae (skunks and stink badgers), Mustelidae (badgers, otters, weasels, and relatives), Odobenidae (walruses), Otariidae (eared seals and sea lions), Phocidae (earless seals), Procyonidae (raccoons and relatives), and Ursidae (bears) (Wilson and Reeder 2005). Within Caniformia, the superfamily Musteloidea consists of Ailuridae, Mephitidae, Mustelidae, and Procyonidae. Terrestrial species of Carnivora occur naturally across the world except in Antarctica,

Australia, New Guinea, New Zealand, and many oceanic islands. The dingo (*Canis lupus*) was likely introduced by humans to Australia during prehistoric times and has since established wild populations. The aquatic pinnipeds (families Odobenidae, Otariidae, and Phocidae) tend to be restricted to colder waters in the northern and southern hemispheres, although some species inhabit warmer waters. The wide variation in body size, life history traits, and behavior across Carnivora make this order particularly suitable for comparative studies.

## Morphology

A distinctive characteristic in most species of Carnivora (hereafter referred to as carnivores) are teeth adapted to cutting and shearing meat. All species except sea otters (*Enhydra lutris*; 3/2), sloth bears (*Melursus ursinus*; 2/3), and pinnipeds have small incisors numbered 3/3. The canines are large, recurved, and pointed. Often a specialized pair of shearing teeth known as the carnassials are present, which consist of the last upper premolar and first lower molar (Fig. 2). Carnassials are less developed or greatly modified in ursids, procyonids, and pinnipeds. The other teeth behind the carnassials vary in number among carnivore families. The jaw joint has a transverse hinge which allows for up and down movement associated with biting and cutting meat but prohibits side to side grinding movement. Other adaptations to carnivory include forward pointing eyes, a large brain, acute sense of smell, flexible vertebral column, and in some species a long tail. Anal and forehead scent glands are present and used in social communication. Anal glands are modified in mephitids and other species to excrete noxious chemicals when threatened. The digestive system is adapted for carnivory and consists of a simple stomach with a short or absent caecum.

Usually five, but occasionally four, clawed digits are present on each foot. Claws are blunt in species such as ursids and canids but sharp and retractable in certain groups including the felids and African palm civet (*Nandinia binotata*).

**Carnivora, Fig. 2** Carnassials of a dog. (Photo by Kreuzschnabel, used by permission under Wikimedia Commons, License: Cc-by-sa-3.0)

Species such as canids and felids are digitigrade and walk on their toes, while others including ursids and procyonids are plantigrade and walk on the soles of their feet. Carnivores are typically fast runners even among the stockier ursids. In particular, some species are highly adapted for cursorial locomotion, such as the cheetah (*Acinonyx jubatus*) which can obtain speeds of  $29 \text{ ms}^{-1}$  (Sharp 1997). Most carnivores are terrestrial, ranging from semi-fossorial to arboreal. The binturong (*Arctictis binturong*) and kinkajou (*Potos flavus*) have prehensile tails that aid in climbing. Several fissiped species are semiaquatic such as river otters and the polar bear (*Ursus maritimus*) or fully aquatic like the sea otter. Pinnipeds are highly adapted for aquatic life with streamlined bodies, insulative blubber, small or absent external ears, and limbs modified as flippers. The families Odobenidae and Phocidae primarily use their front limbs for propulsion through the water, whereas members of the family Otariidae mostly use their hind limbs for propulsion. Carnivores range across several orders of magnitude in body size from the least weasel (*Mustela nivalis*; 35–70 g) to the male southern elephant seal (*Mirounga leonina*; 5,000 kg). Many species exhibit sexual dimorphism with males tending to be larger than females (Lindenfors et al. 2007). Males of most species also have a baculum except notably those of the family Hyaenidae (Nowak 1999).

## Ecology

While the name Carnivora implies this order is strictly meat eating, many species are omnivores and consume substantial amounts of plant material such as the black bear (*Ursus americanus*). Species often specialize or are opportunistic in obtaining prey from a variety of sources or methods including hunting of terrestrial or aquatic prey and scavenging carcasses. A small number are primarily herbivores or frugivores such as the giant panda (*Ailuropoda melanoleuca*) and kinkajou. Carnivores occupy almost all terrestrial and aquatic habitats across their worldwide distribution including forests, grasslands, deserts, tundra, open ice, freshwater lakes and streams, coastal waters, and the open ocean. Space use ranges from nomadic to territorial either by solitary individuals or by a group such as in lions (*Panthera leo*). Population density is highly variable among carnivores, but large-bodied species usually occur at lower density than small-bodied species (Carbone and Gittleman 2002). Juvenile dispersal is typically male-biased, and females exhibit natal philopatry in many species (Clutton-Brock and Lukas 2012). Home range size increases with metabolic needs as determined by body mass and social group size. In addition, carnivores with a greater proportion of meat in their diet have larger home ranges (Gittleman and Harvey 1982). Longevity in the wild ranges from 1 year in smaller mustelids to over 40 years in some pinnipeds.

Carnivores serve a variety of important ecological roles through predation, disease transmission, and plant dispersal (Ripple et al. 2014; Roemer et al. 2009). Apex predators impact ecosystems through trophic cascades, directly reducing prey abundance or altering their behavior, which in turn alters plant communities and their associated species. Large-bodied carnivores can be keystone species in ecosystems, increasing the overall species diversity through trophic cascades. For example, wolves (*Canis lupus*) change the abundance and behavior of large herbivores, leading to increases in woody riparian plants and associated animal species such as beaver (*Castor canadensis*) and migratory songbirds (Ripple

and Beschta 2012). Smaller carnivores can serve as important seed dispersers as a greater proportion of their diet often derives from plant material than larger carnivores. In Spain, foxes and mustelids feed on the fleshy fruit of *Prunus mahaleb* and typically disperse seeds greater distances than birds (Jordano et al. 2007). Diseases such as parvovirus, canine distemper, and rabies are reported in almost all terrestrial carnivore families. Smaller carnivores that occur at greater densities often serve as disease reservoirs that facilitate transmission to humans or domestic animals (Deem et al. 2000; Krebs et al. 2003; Steinell et al. 2001).

## Behavior

Studies of domestic and wild carnivores have revealed sophisticated levels of cognition such as forming natural categories, discriminating quantities, recognizing cues of human emotion, and discriminating kin (Vonk and Leete 2017). Badgers and sea otters are known to use rudimentary tools. Many behaviors are driven by their carnivorous life history. Brain size relative to body size is largest in species that hunt vertebrates, intermediate in herbivores, and smallest in insectivores. The relative cerebrum size tends to be larger in more socially complex species (Holekamp et al. 2015).

Most carnivore species are solitary or form pairings for mating, but a few species are gregarious. Social carnivores (hyenas, wolves, etc.) form extensive social hierarchies where position is influenced by factors such as sex, age, and kinship. Social position can determine access to resources and breeding opportunities (Creel 2005). Mating systems range from serial monogamy to extreme polygyny such as in the southern elephant seal where males defend and breed with large harems of females (Fabiani et al. 2004). Once reaching sexual maturity, females typically give birth once a year, but a small number of species may give birth to multiple litters per year such as weasels or go several years between births such as walrus (*Odobenus rosmarus*, 5–6 years between births). Gestation ranges from 49

to 113 days; however, delayed implantation in ursids, pinnipeds, and some mustelids greatly lengthens time between mating and birth. Litter size ranges from 1 to 13 young. At birth, carnivore young range from altricial as in bears where cubs are born blind and completely dependent on the mother to precocial as in some seal species where pups can swim within a few minutes of birth. The mother nurses and cares for the young, but the father also provides parental care in some species. Some canid and mongoose species practice cooperative breeding which can take the form of allo-nursing, feeding of prey, and other parental care duties (Lukas et al. 2012). Young may remain with the parents for extended periods after weaning to learn how to hunt prey.

Species range from nocturnal to diurnal in activity. Hunting behavior varies depending on habitat and targeted prey but often involves stealth and sprinting to subdue prey. Some species such as the cougar (*Puma concolor*) lie in wait and ambush passing prey, whereas wolves and lions actively pursue prey over longer distances. Social species may employ group hunting tactics allowing them to restrain and kill larger prey (Bailey et al. 2013). Some ursids and the European badger (*Meles meles*) engage in shallow torpor during winter by reducing their body temperature  $\sim 5^\circ\text{C}$ , whereas striped skunks (*Mephitis mephitis*) engage in daily torpor during cold periods (Geiser 2010). Pinnipeds are adapted to foraging at depth underwater for extended periods without supplemental air. The most extreme diving behavior is observed in Weddell seals (*Leptonychotes weddellii*) which can remain under water over an hour and reach depths of 600 m (Schusterman 1981).

Carnivores use visual, acoustic, and odor signals to communicate. In particular, their well-developed olfactory system allows for a variety of signals (reproductive condition, identity, and territory) to be communicated via gland secretions, urine, and feces (Gorman and Trowbridge 1989). Acoustic signals primarily from vocalizations are used in many species to immediately communicate at close (e.g., alarm calling or growling) or long distances between groups or individuals (e.g., howling in wolves) (Peters and Wozencraft

1989). Pinnipeds rely heavily on vocalizations produced above and below the water to communicate information and identity among individuals (Schusterman and Van Parijs 2003).

## Conservation

According to the International Union of Conservation of Nature (IUCN) of the 285 Carnivora species assessed, 5 were extinct, 8 were critically endangered, 24 were endangered, 39 were vulnerable, 27 were near threatened, 163 were of least concern, and 19 were data deficient. Overall 26.7% of Carnivora species were threatened or extinct (IUCN et al. 2008). Major threats include habitat loss and degradation, human persecution, overexploitation, and depletion of prey (Cardillo et al. 2004; Crooks et al. 2011).

## Carnivora Families

A brief overview of each Carnivora family is provided below based on reviews in Hunter (2011), Nowak (1999), and Vaughan et al. (2015). Taxonomy is based on Wilson and Reeder (2005).

### Suborder Feliformia

Eupleridae: This Malagasy carnivore family includes eight species in seven genera that are only found in Madagascar. Three of the species are civet-like and the other five mongoose-like in appearance. They feed on invertebrates and small vertebrates. They range from 500 g to 12 kg in body mass. The nocturnal fossa (*Cryptoprocta ferox*) is the largest member of the family and is cat-like with retractable claws. It is arboreal and eats vertebrates including small lemurs.

Felidae: The cat family consists of 40 species in 14 genera that are distributed worldwide except the Arctic, Australia, Antarctica, Madagascar, and most oceanic islands. Cats are highly specialized for predation with well-developed carnassials, retractable claws (except in cheetahs), strong forelimbs, and concealing color patterns. They are typically good swimmers and agile climbers

with well-developed sensory systems. They have a tapetum lucidum within the eye that creates superior night vision. They eat a variety of prey including fish, mollusks, and small and large vertebrates. Body mass varies among species from 1 to 325 kg. Many species are solitary, but some form pairs or groups.

Herpestidae: The mongoose family includes 14 genera and 33 species. They occur in southern Asia, southeastern Europe, and Africa and are typically the most common carnivores across their range. They are long-tailed and long-bodied ranging from 270 g to 5 kg. They have small, elongated heads with pointed snouts and short ears. Herpestids are primarily insectivorous and found in forests to open deserts. Most species are terrestrial, but a few are semiaquatic. Some species such as meerkats (*Suricata suricatta*) live in groups with complex social systems.

Hyaenidae: Members of this family include the aardwolf (*Proteles cristata*) and three hyena species in three genera. They are restricted to grassland, bush country, and open forests in Africa, Turkey, the Middle East, and India. They are the most specialized carnivore family for carrion feeding. The hyena species (25–86 kg) are heavily built with strong jaws, well-developed carnassials for crushing bones, and forelimbs longer than hind limbs. While the other 2 hyena species live solitary or in small groups, spotted hyenas (*Crocuta crocuta*) live in groups of up to 80 individuals and have complex social behaviors. Aardwolves (9–14 kg) are more delicately built and secrete a noxious fluid from anal glands when threatened. They primarily feed on termites and other invertebrates.

Nandiniidae: The only species in this family, the African palm civet, occurs across sub-Saharan Africa as far south as Angola and Zimbabwe. African palm civets are arboreal and omnivorous, feeding primarily on fruit. They weigh from 2 to 5 kg. They are nocturnal and live solitarily.

Viverridae: The viverrid family includes 35 species of civets, genets, linsangs, and relatives in 15 genera. They occur in southern Europe, southern Asia, and Africa. They have long tails and short legs and range in body mass from 600 g to 20 kg. Viverrids are agile climbers, and some

species have retractable claws. The binturong is the only member of this family that has a prehensile tail. Viverrids are primarily carnivorous and feed on small vertebrates and invertebrates. Several species are semiaquatic and feed on fish and amphibians. Most viverrids are nocturnal and live solitarily.

### Suborder Caniformia

**Ailuridae:** The sole member of this family is the red panda (*Ailurus fulgens*). This arboreal species (3–6 kg) is found in isolated forests of northern Burma and South Central China. They have an enlarged radial sesamoid bone (false thumb) that assists in grabbing branches and handling food. They are primarily herbivores that feed on leaves and other plant material. Red pandas are not closely related to the giant panda but eat bamboo leaves in a similar manner.

**Canidae:** The canid family consists of 13 genera and 35 species of dogs, foxes, jackals, wolves, and relatives. They occupy a diverse range of habitats from arctic to tropical on all continents except Australia, Antarctica, Madagascar, and most oceanic islands. Most are omnivorous, but a minority are mainly carnivorous and a few insectivorous. Body size ranges from 2 to 80 kg. Canids typically have a long rostrum that is associated with an exceptional sense of smell. They usually have well-developed carnassials and postcarnassial teeth that have crushing surfaces reflecting an omnivorous diet. Several species live in social groups, but only wolves hunt cooperatively.

**Mephitidae:** The mephitid family includes ten skunk and two stink badger species in four genera. Skunks are native to North and South America, whereas the stink badgers are endemic to Indonesia, Malaysia, and the Philippines. Mephitids feed on a variety of animal material including small vertebrates, invertebrates, and carrion. They are small bodied (0.5–4 kg), nocturnal, and have conspicuous white and black markings that warn predators. When threatened they spray a noxious fluid from anal glands that causes irritation. They are solitary in nature.

**Mustelidae:** The mustelid family consists of 59 species of badgers, otters, weasels, and

relatives in 22 genera. They inhabit all land masses except Australia, Antarctica, Madagascar, and most oceanic islands. Mustelids are small to medium sized (25 g to 45 kg) with a long body and short limbs. The skull has a long braincase with a short rostrum. They are primarily carnivorous and occupy a variety of habitats including forests, grasslands, deserts, and tundra. Many mustelids are agile hunters that aggressively chase prey above and below ground. River otters are semiaquatic, and the sea otter is almost fully aquatic.

**Odobenidae:** The walrus family has only one living species, *Odobenus rosmarus*. They inhabit arctic waters of the Atlantic and Pacific Oceans. Walruses have a thick, nearly hairless body (400–1,700 kg) and rounded head with thick skin and an insulative blubber layer. The upper canines are modified into elongated tusks that grow throughout life and are used for fighting. They have a highly sensitive mustache of thick bristles that is used to search for mollusks on the seafloor. Walruses are polygynous and can congregate in large groups of more than 1,000 individuals.

**Otariidae:** The otariid family contains 7 genera and 16 species of eared seals and sea lions. They are found along the coasts of the Pacific Ocean and areas of the South Atlantic and Indian Oceans. The otariids are less modified for aquatic life than phocids and can use their hind flippers for terrestrial locomotion. Body mass ranges from 60 to 1,000 kg with significant sexual dimorphism in some species. They have small external ears and oar-like flippers with small claws. They are strictly carnivorous feeding on fish and squid. Otariids are typically gregarious, forming large breeding colonies of thousands of individuals.

**Phocidae:** The phocid family consists of 19 earless seal species in 13 genera. They occur in polar and temperate oceans along coastlines and ice fronts. Some species live in tropical waters or inland bodies of water. They are highly specialized for aquatic life with streamlined bodies (65–5,000 kg), insulative blubber, and no external ears. Most phocids feed on fish, cephalopods, and mollusks. Two species including the crabeater seal (*Lobodon carcinophagus*) filter feed on crustaceans and plankton through specialized cheek

teeth. Some species are monogamous, whereas others are polygynous such as elephant seals that form large breeding harems and exhibit extreme sexual dimorphism.

**Procyonidae:** The procyonid family includes 14 species of raccoon, ringtails, and relatives in 6 genera. They occur in North and South America primarily in forested temperate and tropical environments. Body mass ranges from 1 to 20 kg. They have reduced carnassials with poor shearing abilities. Procyonids are predominately omnivores that feed on seeds, fruit, invertebrates, and small vertebrates. In the tropics, they are primarily arboreal, such as the kinkajou that has a prehensile tail. Many species are nocturnal; however, coatis which live in groups are often diurnal.

**Ursidae:** The bear family consists of five genera and eight species. They are historically found throughout North America and Eurasia and the Malay Peninsula, the Atlas Mountains of North Africa, and the Andes of South America. Ursids occupy many habitats from arctic ice floes to tropical forests feeding on plants, invertebrates, vertebrates, and carrion. They are primarily omnivores except for the carnivorous polar bear and the giant panda that feeds mostly on bamboo. The ursids are powerfully built (27–780 kg) with muscular limbs, recurved claws, and a large skull with poorly developed carnassials. In colder areas, some bear species gain substantial amounts of fat and enter shallow torpor during the winter.

## Carnivore (Diet)

Jacqueline Boyd  
 Skinner's Pet Foods, Stradbroke, UK

## Synonyms

[Flesh-eater](#); [Meat-eater](#); [Predator](#)

## Definition

Carnivore (diet) refers to any species that ingests animal tissues, either wholly or in part.

## Introduction

A **carnivore** is defined as an organism that consumes animal tissue. With specific reference to the carnivore diet, the term relates to foodstuffs ingested, digested, absorbed, and utilized by an organism and identifies that ingested foodstuff consists wholly, or in part, as tissues derived from other animal species.

The dietary niche inhabited by a given species is an important aspect of ecological classification.

What nutrients an animal requires and how an animal acquires those nutrients constitute the dietary niche of a given species. Carnivory is viewed as one of the three major dietary classifications, the other two being omnivory and herbivory. The term carnivore is derived from the Latin *carn*, meaning “flesh,” and *vor*, “to devour,” and essentially means “flesh eating.” Consequently, carnivorous organisms obtain their dietary nutrient and energy requirements from animal tissues, either exclusively or in part. Those animal tissues can be insect (insectivore), invertebrate (invertivore), avian, lizard, amphibian, fish (piscivore), or mammalian in origin. Hematophagy (the consumption of blood) can also be viewed as a form of carnivory. Carnivory is viewed as forming the third trophic level, and carnivores are typically regarded as secondary consumers, although carnivores that prey and feed on other carnivorous species are typically classed as tertiary consumers and apex predators.

### Evolution of the Carnivore Dietary Strategy

For one species to consume the tissues of another, specific adaptations are required to acquire, consume, and effectively digest the tissues of the ingested species. The consumption of animal tissues represents an effective form of both energy and nutrient acquisition. Indeed, carnivory has appeared across different taxonomic orders, in several mammalian clades (Van Valkenburgh 1999), and at multiple times during evolutionary history. The repeated appearance of carnivory as a dietary strategy demonstrates its success as a nutritional niche, with the consumption of animal tissues representing a nutrient-rich food source in terms of protein, fat, vitamins, minerals, and other key nutrients. Carnivory can also be viewed as an effective dietary strategy that did not necessitate the evolution of the highly specialized additional physical, physiological, and microbial adaptations typically needed to digest vegetation, as observed in the ruminants and hindgut fermenters (Stevens and Hume 1995).

However, the carnivore dietary strategy has been dependent upon the development of key evolutionary adaptations for successful predation, scavenging, ingestion, and processing of food-stuffs. Consequently, a range of physical, physiological, metabolic, and behavioral characteristics are observed across those species with a carnivorous diet. Indeed, the characteristic dentition of members of the mammalian order Carnivora, that includes enlarged canines and a carnassial apparatus, is also evident in the fossil record of the family Miacidae, the earliest members of this order that appeared over 40 Ma (Wang and Telford 1994). Indeed, evidence suggests that there is striking similarity in dental adaptations for carnivory in different groups of flesh-eating species, both extinct and extant (De Muizon and Lange-Badre 2007). There is now a wide variety of adaptations supportive of carnivory that can be identified in extant species, and the consumption of animal tissues remains widespread in nature.

### Classification of Carnivores

Carnivorous organisms can be broadly classified based on the approximate percentage of animal-derived tissue in their diet. Contrary to popular belief, not all carnivores have a diet that exclusively consists of tissue derived from other animal species. Carnivorous species with greater than 70% of their diet consisting of animal tissue are defined as hypercarnivores; those with between 30% and 70%, mesocarnivores; and species with a dietary composition of less than 30% animal tissue, hypocarnivores (Van Valkenburgh 2007). It is also worthy to note that the term mesocarnivore is sometimes used to refer to carnivorous species that are of a medium morphological size, such as foxes and other canid species, for classification purposes.

### Carnivorous Organisms

The term carnivore is often used to refer to the mammalian order Carnivora, which includes the terrestrial flesh-eating mammals (suborder

Fissipedia), such as canids and felids, and the aquatic mammals that feed on fish (suborder Pinnipedia), such as seals and walruses. However, a carnivore diet is not exclusive to this order, and equally, not all members of Carnivora are obligate hypercarnivores (i.e., they absolutely require animal tissues in their diet), and some demonstrate substantial adaptations for other dietary niches. The giant panda (*Ailuropoda melanoleuca*) is one such species, a specialist bamboo feeder that retains the innate characteristics of a carnivore digestion system but has evolved other characteristics associated with the digestion of cellulose, including a symbiotic microbiome population, capable of cellulose metabolism (Zhu et al. 2011).

There are also many species with a carnivorous dietary strategy that are not members of the order Carnivora, including birds, insects, lizards, amphibians, fungi, fish, and even some plants. Carnivorous plant species trap and digest insects and small animals as a source of nutrients and energy. These plant species demonstrate high levels of physiological and morphological similarity as adaptations in support of carnivory (Ellison and Gotelli 2009). Genomic analysis also reveals molecular similarities in carnivorous plant species, suggesting convergent evolution and limited evolutionary pathways toward plant carnivory (Fukushima et al. 2017).

Similarly, the class Insecta contains approximately 14,000 species known to feed on blood (Adams 1999). These organisms are highly adapted for blood feeding and are responsible for significant levels of morbidity and mortality in human and animal populations because of disease transmission, annoyance, and reduced productivity (Lehane 2005). Consequently, while carnivory is often associated with mammalian members of the order Carnivora, it is a dietary strategy not exclusive to that order, and the consumption of animal tissues can be observed in a much wider taxonomic range of species.

Indeed, evidence suggests that “opportunistic carnivory” is sometimes observed in species otherwise considered to be entirely herbivorous in their dietary strategy, without deleterious consequences. Domestic rabbits have been observed to consume animal carcasses suggesting both

opportunity and behavioral adaptations (Clauss et al. 2015). Similarly, snowshoe hare (*Lepus americanus*) have been observed to scavenge from carcasses of lynx and other hare, possibly as a strategy to deal with dietary inadequacy, especially in winter months (Peers et al. 2018). Deer have also been noted to consume tissues and indulge in osteophagia (consumption/chewing of bone) from carcasses in an opportunistic manner (Meckel et al. 2017). Evidence of species not traditionally viewed as carnivorous, consuming animal tissues in this way, demonstrates the diversity of species in which a carnivore diet (either whole or in part) can be observed.

### Obligate Carnivores and Facultative Carnivores

Clearly, the proportion of animal tissue in the diet of carnivores varies. Obligate carnivores are those species that depend entirely upon animal tissue for the supply of their nutrient requirements, whereas facultative carnivores will also consume and obtain nourishment from non-animal-derived material. The definition of facultative carnivore or omnivore remains obscure, with the amount of animal-derived dietary material versus plant-derived material not being fully defined. However, facultative carnivores typically demonstrate physical adaptations in support of carnivory, such as a relatively short, simple gastrointestinal tract, elongated canine teeth, and a carnassial apparatus that might not be observed in a more omnivorous species such as swine (*Sus scrofa*). Obligate carnivores (e.g., felids and mustelids) typically demonstrate specific metabolic and biochemical specializations that further limit their ability to survive without animal-derived material in their diet (Legrand-Defretin 1994). This has ramifications in considering ecological niche survival and in the formulation of diets for captive and companion animals, where obligate carnivores have very specific nutritional requirements that need to be fulfilled in prepared dietary provision.

Conversely, while facultative carnivore species typically retain physical and physiological characteristics of carnivory (dentition, simple digestive

system, scavenging/hunting behavior), some species also demonstrate genetic signatures that are indicative of an evolutionary adaption to other sources of nutrition. This supports a nutritional ecological niche that includes the consumption of a range of foodstuffs and an ability to derive appropriate nourishment from them. The domestic dog (*Canis lupus familiaris*), for example, has a molecular signature supporting adaption to the presence of carbohydrate, specifically starch, in their diet (Axelsson et al. 2013). These findings support the development of specific dietary adaptations in otherwise carnivorous species, based on their ecological niche and parallel evolution with other species, including humans (Perry et al. 2007).

## Nutritional Requirements of the Carnivore

The obligate carnivore absolutely requires animal tissue as a source of key nutrients in their diet. Correspondingly, these species (felids are particularly well documented and studied) demonstrate a biochemistry and metabolism with limited intrinsic biosynthesis of specific compounds. These species are metabolically adapted for higher levels of protein metabolism and a limited ability to metabolize dietary carbohydrates (Zoran 2002). Their requirement for maintenance of glucose levels in the body is predominantly met via gluconeogenesis from protein precursors, rather than via the provision of dietary carbohydrates. This contrasts with many facultative carnivores that appear to have evolved metabolic strategies and pathways that permit the biosynthesis of many key compounds from alternative precursors, meaning that a dietary source of animal-derived nutrients is not always essential for survival.

For example, felids are well described as lacking the ability to synthesize adequate levels of both arachidonic acid and vitamin A (MacDonald et al. 1984). Consequently, an adequate dietary supply of these substances must be provided. A diet based on animal-derived tissues typically fulfils these nutritional requirements. Similarly, the amino acid taurine is also essential in feline diets and fox diets. Taurine is critical for several normal bodily

functions, and deficiency symptoms typically manifest as feline central retinal degeneration (FRCD), reproductive issues, impaired fetal development, and heart issues, notably dilated cardiomyopathy (DCM). Taurine biosynthesis is extremely limited in obligate carnivores, in contrast to most herbivores and omnivores (Chesney 1985), supporting their dietary need for taurine. This is a consequence of the feline liver having a limited enzymatic ability to convert the precursor amino acids methionine and cysteine to taurine, combined with an obligate loss of taurine via the feces and intestinal microbe degradation (Morris and Rogers 1992). Mammalian tissue is rich in taurine, especially the brain, heart, and skeletal muscle, meaning that obligate carnivores will typically obtain enough dietary levels, providing there is adequate consumption of animal-derived tissue.

However, taurine appears to be dispensable in the diets of facultative carnivores such as the domestic dog that ingest adequate amounts of sulfur-containing amino acids to support taurine biosynthesis (Kramer et al. 1995; Delaney et al. 2001). Conversely, diets low in protein (Sanderson et al. 2001) or low in bioavailable precursor amino acids (Backus et al. 2003) can result in taurine deficiency and the appearance of clinical signs such as DCM.

Similarly, the maned wolf (*Chrysocyon brachyurus*) is a largely frugivorous canid of South America and in captivity is typically fed a higher proportion of animal tissue than would naturally be encountered. However, problems with cystinuria in captive individuals and the feeding of formulated diets to reduce this risk resulted in severe reductions in plasma taurine concentrations (Childs-Sanford and Angel 2006). Taurine supplementation to such diets for the captive maned wolf is now indicated. More recent reports of cases of DCM in domestic dogs with a correlative link to taurine metabolism, apparently linked to the formulation of specific commercial diets (Freeman et al. 2018), have raised further discussion about the dietary need for taurine in facultative carnivores, although it is likely that a range of biological variables including physiological, metabolic, genetic, and dietary factors are involved, and further investigation is required.

## Characteristics of the Carnivore for Diet Acquisition and Processing

Organisms with a carnivore dietary strategy demonstrate specific adaptations to enhance their ability to obtain dietary animal tissue and nourishment from it. These adaptations are characteristic of many carnivorous species and are useful classification tools. However, the range of species in which carnivory is observed does make generalizations difficult.

Animal tissue included in the diet of carnivores can be obtained either via hunting and predation or by scavenging. Specific physical, physiological, behavioral, and metabolic adaptations are observed in carnivorous species as a result and are functionally important for the acquisition of dietary material (e.g., by hunting) as well as the processing of animal tissue in the digestive tract. The dentition of vertebrate carnivores is a prime example of such adaption, with highly specialized teeth specialized for killing, ripping, tearing, bone crushing, and varied degrees of grinding ability. Notably, animals with a more omnivore-like dietary strategy, such as the domestic dog (*Canis lupus familiaris*), have more teeth (42 compared to 30) than obligate carnivores such as felids. This is attributed to an increased number of molars and premolars, permitting increased mechanical processing of ingested material. Genomic signatures of carnivores also indicate a clear adaptation for the consumption and digestion of animal tissue, alongside adaptations for successful predation and other associated attributes (Kim et al. 2016).

Carnivorous mammalian species demonstrate flexibility in the diversity of prey consumed and thus in the adaptations required. Species that are hypercarnivorous (such as the polar bear, *Ursus maritimus*) tend to be large, show specific predatory adaptations and higher hunting energetic costs (Carbone et al. 2007), and demonstrate dentition capable of dealing with the processing of bones and other difficult tissues, as seen with early hyaenid carnivores (Werdelin 1989). Species that tend toward a hypocarnivorous strategy are typically small to medium-sized and often undertake frequent, solitary hunting behavior. Small carnivores appear to eat to gut capacity regularly, in contrast to larger species who

typically demonstrate reduced predation frequency because of both gut capacity and increased prey size (De Cuyper et al. 2019), revealing that both ecological (including temporal and spatial) and physiological factors impact on dietary choices.

For carnivores that are dependent in hunting for prey acquisition, physiological characteristics permitting strength, sensory awareness, and speed are critical, in addition to behavioral adaptations likely to enhance hunting success. Behavioral adaptations may take the form of cooperative hunting strategies or solitary strategies. Scavenging behaviors can also be observed in species that do not hunt or in an opportunistic way by those that would otherwise hunt for prey.

The typical mammalian carnivore digestive system is short and simple in contrast to the highly sacculated and specialized digestive systems observed in many herbivorous species. This corresponds to the high digestibility of the carnivore's diet compared to herbivores and the lack of requirement for prolonged retention of ingesta or significant levels of microbial fermentation. The stomach is considered simple but is often capable of expansion to permit the ingestion of larger prey items (Hume 2002). The small intestine is typically short, although it is notably longer in marine carnivores compared to terrestrial carnivores (Stevens and Hume 1995). If present, the caecum tends to be small, and the colon is also characteristically short.

In other species, such as carnivorous birds, amphibians, reptiles, and fish, the digestive systems are also simple and short, reflective of the high digestibility of ingesta. Carnivorous birds (especially raptors) have specialized beaks and talons to aid the separation of indigestible portions of prey or scavenged material prior to ingestion. Where indigestible material is consumed by carnivorous birds such as owls, it is separated in the gizzard and then egested as a formed "pellet" (Klasing 1998).

## Conclusion

The carnivore diet is one that consists of tissues from other animals, either wholly or in part. Those

tissues can be obtained via predation or scavenging. The carnivore dietary strategy is observed in a wide range of taxonomic orders and appears to have arisen multiple times during evolutionary history. As a dietary strategy, carnivory represents a dietary niche that exploits and utilizes highly digestible foodstuffs and requires few specific system adaptations to support prolonged retention, microbial fermentation, and other mechanisms to permit the digestion of otherwise indigestible material, as seen in many herbivorous species.

Predation is associated with the development of specific behavioral and physiological adaptations to enhance hunting success, although for many predators, prey availability is affected by temporal, spatial, and other ecological factors. Many predators are obligate carnivores and require animal tissues to supply key nutrients that cannot be synthesized within the body. Consequently, many of these species would be classed as hypercarnivores, with animal-derived tissues forming most of their dietary intake. Scavenging behavior is also observed in many species that actively ingest other animal tissues and can be either on an opportunistic or intentional basis, occasionally in species that would otherwise be unexpected to actively consume animal tissues.

Carnivory is a successful dietary strategy. It is observed across a wide diversity of species, which demonstrate a wide range of specific adaptations to support this life and diet strategy. Similarities are evident however, even across orders, at the physical, molecular, and nutrient requirement levels.

## Carrier

Neelabh

Department of Biotechnology, SR Institute of Management and Technology, Lucknow, Uttar Pradesh, India

Department of Zoology (MMV), Institute of Science, Banaras Hindu University, Varanasi, Uttar Pradesh, India

## Synonyms

Genetic carrier; Hereditary carrier

## Introduction

In genetics, a carrier or a hereditary carrier is referred to an organism that has inherited or has been passed on with a recessive allele for a genetic trait or gets that recessive allele due to mutation but does not display that trait in its phylogeny. However, carriers can pass on that recessive allele to their offspring and their offspring can either show the recessive trait or not in their phylogeny

|   |                           |                            |
|---|---------------------------|----------------------------|
|   | A                         | a                          |
| A | AA<br>Homozygous dominant | Aa<br>Carrier              |
| a | aA<br>Carrier             | aa<br>Homozygous recessive |

**Carrier, Fig. 1** Punnett square depicting a cross between two genetic carriers and showing a 25% probability of an offspring being homozygous recessive

depending upon the allele that it received from the other parent. If the allele received from the other parent is a dominant allele then the offspring would again be a carrier but if the allele received from the other parent is a recessive allele then the offspring will show the recessive trait in its phylogeny (Krasnewich 2017). Henceforth, it can be complied that the probability of two carriers (of a disease) having an offspring with a disease is 25%. This can be understood by the Punnett square diagram shown in Fig. 1.

In the study of genetic diseases, it is important to determine the frequency of the carriers prevalent in the diseased population. For this Hardy-Weinberg formula was devised which applies to a gene with exactly two alleles and the frequency of those alleles are related to the frequency of their three genotypes in a large population.

For instance, if “p” is the frequency of the dominant allele “A” and “q” is the frequency of recessive allele “a,” then according to Hardy-Weinberg principle the terms  $p^2$ ,  $2pq$ , and  $q^2$  are the frequencies of the genotypes AA (homozygous dominant), Aa (heterozygous or carrier), and aa (homozygous recessive) respectively (Andrews 2010).

Carriers or organisms with heterozygous genotype have an important role to play in case of the genetic diseases that are caused by the recessive allele.

1. **X-Linked Hemophilia** (Bolton-Maggs and Pasi 2003; National Library of Medicine 2012a): X-linked hemophilia occurs due to the presence of an abnormal allele of a gene present on the X chromosome that is required for the blood clotting. Since males have only one X chromosome therefore, if a male encounters this altered allele then he will suffer from hemophilia whereas in case of females two possibilities can occur:

- If the female gets both the altered alleles for the said gene then she will suffer from hemophilia.
- If the female has one altered and the other “normal” allele, then the female would be an asymptomatic carrier. This female would continue to pass on this altered allele to half of her offsprings.

2. **Cystic Fibrosis** (National Library of Medicine 2012b): Mutations in the cystic fibrosis transmembrane conductance regulator genes (CFTR gene) lead to cystic fibrosis. It is an autosomal recessive disorder. The impact of this disease in the Caucasian people can be understood by the fact that 1 in every 25 individual was a carrier of this disease which means that they possess one mutated CFTR allele and one “normal” CFTR allele. Carriers remain unaffected in this disease as the “normal” CFTR allele codes for a normal protein which compensates for the mutated CFTR allele. Cystic fibrosis is only seen in people who have both mutated alleles for the CFTR gene (O’Sullivan and Freedman 2009).

3. **Sickle Cell Anemia (SCA)**: Sickle cell anemia is also an autosomal recessive disorder. It is a very common disease in the African Americans. SCA comprises of the red blood cells and their ability to carry oxygen. Unlike the normal red blood cells which are smooth, round and are easily motile through the vessels, red blood cells of the patients in this case become stiff and sticky. Moreover, their shape transforms to that of a sickle and hence causes clustering leading to a blockage of the flow of blood. Carriers in this case also have a normal allele along with an altered allele. The normal allele compensates for the function of the

altered allele and henceforth carriers are typically asymptomatic (Luzzatto 2012).

### **Heterozygote/Heterozygous Advantage:**

There are certain conditions in which the heterozygous genotype is more advantageous than either homozygous dominant or homozygous recessive genotype. These conditions are described by the heterozygote advantage. Overdominance is a particular case of heterozygote advantage in which the phenotype of the heterozygous individual is far more different than the range of the homozygous dominant and homozygous recessive individuals, thus providing more fitness to the heterozygous individual.

Heterozygote advantage is the fundamental mechanism for the heterosis or hybrid vigor which describes the increased affectivity of any biological quality in case of a hybrid offspring. Some examples of the heterozygote advantage are:

1. In case of malarial outbreaks in the SCA population, the heterozygous individuals have a distinct advantage over the homozygous recessive and the homozygous dominant individuals. The malarial parasite resides in the red blood cells of the infected patients and triggers an abnormal drop in the oxygen level in the cells. In case of carriers, this sudden drop in the oxygen level catalyzes a reaction through which the infected cells experience a sickle cell condition and are removed from the circulation resulting in the inhibition of the progress of infection. In case of patients having both the altered alleles for SCA might survive the malarial outburst but will eventually die of SCA unless they get medical attention. In case of individuals having both the alleles of “wild type” or homozygous dominant for SCA will not be affected by the SCA but are more susceptible to death by malarial before they successfully pass on their genes to their offsprings. Henceforth, it can be concluded that in case of SCA heterozygous individuals are more resistant and have a better chances of survival during malarial outbursts (Ringelmann et al. 1976).
2. In case of cystic fibrosis, researchers have shown that the heterozygous individual has

an advantage over both the homozygous individuals with respect to resistance against tuberculosis, respiratory advantage and also in case of cholera which remains debatable (MacKenzie 2006; Högenauer et al. 2000).

Other examples of heterozygote advantage include triosephosphate isomerase deficiency (Ralser et al. 2006), resistance to Hepatitis C virus infection (Hraber et al. 2007) etc.

## **Conclusion**

A carrier in genetics is referred to an organism that is genotypically heterozygous for a particular trait. It comprises of a recessive allele which has been either passed on to it or undergone some mutation. Carriers have a humongous role in case of genetic diseases. They can pass on their altered alleles to their offsprings without themselves being symptomatic of the disease. Therefore, their analysis and determination in a particular population becomes increasingly important and is done through the Hardy-Weinberg law. Additionally, a heterozygous individual might be open to some advantages or increased fitness which makes them more resistant to either the homozygous dominant or homozygous recessive individuals termed as heterozygous advantage.

## Cartesian Dualism

William T. Leach

Truman State University, Kirksville, MO, USA

## Definition

A philosophic doctrine originating from Descartes stating that there are two categories of things in existence, the physical and the mental.

## Introduction

Cartesian dualism was created by Descartes, a seventeenth-century Frenchman who made significant contributions to philosophy, mathematics, and science. He is primarily known as the father of modern philosophy and a key figure in the scientific revolution due to his mathematical legacy, weakening of the church’s influence on philosophy, and inspiring future scientists like Newton. One of his greatest contributions to philosophy was his revival of several key philosophy debates from the Greeks, including that of monism versus dualism. The doctrine of monism asserts that everything in existence can fit within one category, or type, of “thing.” Monism has two primary facets: materialism and idealism. Materialism is the theory that all things are physical in nature. Idealism is the less popular belief that all things are primarily from a mental plane. Sometimes this is characterized as coming from an ideal plane. Dualism is the opposing view that there are two distinct kinds, or types, of things that are needed to characterize all of existence. While there are many proposed pairs of types, the distinction remains between physical and non-physical things.

## The Context of Cartesian Dualism

Descartes was both a philosopher and scientist during a critical point in the renaissance. While religion and theology had dominated philosophy, society, and acceptable knowledge, science was now rapidly expanding both its tools and its acclaim. Descartes began to explore the relationship between the mind and the body. He held both theology and religion, as well as mathematics and the scientific study of the laws and nature, in high regard but struggled to bring such disparate methods together. For him, this presented the need for dualism to explain the validity of both the aforementioned as they do not focus on the same type of thing.

## The Creation of Cartesian Dualism

In his book *Discourse on the Method*, Descartes famously introduces his doubt argument, with the

well-known conclusion “Cogito ergo sum” or “I think therefore I am” (Descartes 1637/2007, p. 16). This lays the groundwork for dualism and the necessity of dualism. In the doubt argument, Descartes sets out a thought problem he utilized to search his own beliefs and purge any that he was not confident were true. Through this process of doubt, Descartes introduces many challenges to the truth of our own experience and thought, such as the idea that our current existence is just a dream and a malevolent demon giving us our sensations and perceptions and tricking us into believing that they are our own. This made Descartes doubt the vast majority of his beliefs. He could doubt all of physical reality, all of his sensations, but believed he could not doubt that he himself is mentally doubting all of these things. From this, he is assured that he exists because he is committing this act of doubting. If he can doubt all that is physical, but he cannot doubt this act his mind is committing, then there are different properties, and thus two different types of things are needed (Descartes 1637/2007). This argument was a convincing defense of the necessity of dualism, allowing Descartes to move the Greek notion of dualism away from matter and intellect and move it toward matter and consciousness. This is sometimes referred to as Descartes first argument for the separation of the mind and body.

In the Sixth Meditation of Descartes’ *Meditations on First Philosophy*, he offers additional arguments to reinforce that the mind and body are separate. Descartes asserts that if two things are perceived to be separate, and to have different properties, they are not the same type of thing (Descartes 1641/2007, p. 30). This is followed by Descartes stating that he perceives with certainty that he exists as a thinking thing. He also perceives with near certainty that his physical body is not a thinking thing (Descartes 1641/2007, p. 30). From this he derives that the mind and body must be different because they have different properties, and he perceives them as different. Secondly, Descartes asserts that while the physical body is divisible into parts that then make up the whole, the mind is not indivisible, once again showing different properties that require them to be separate types of things (Descartes 1641/2007, p. 33). With these arguments,

Descartes set the stage for the modern mind-body problem, where the relationship and distinction between what is part of the mind and what is part of the body, or if they are even truly separate, are still contended.

Once the mind is considered separate from the body though, many questions are still left unanswered. In a later book *Treatise on Man*, Descartes more directly outlines his new form of dualism. He explains that the human body was created by God and works like an “earthen machine” (Descartes 1998, p. 1). Since the body is made of matter, it can be explained in purely mechanical terms and is subject to the laws of nature, such as those outlined by physics, like a machine is made up of various systems to perform specific operations such as breathing, eating, and walking (Descartes 1998). This mechanistic view of how the body functions seems very in line with our modern scientific perspective of our biological systems, as well as neurological systems and reflexes. Descartes himself was the first to propose a mechanism for which human behavior could be produced from and proposed the simple reflex was the building block for the behavior of the body and for animals that did not possess a mind explained their behavior completely (Skinner 1931). Similar to his contemporary, William Harvey, who first proposed the circulation of blood in *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus*, Descartes proposed a system within the body that circulated animal spirits where reflex actions resulted from a stimulus and the flow of animal spirits to nerves it caused (Descartes 1998, p. xxiv). This gave him a rough system that explained physical beings in terms of machines, for both humans and animals, and explained their actions including that of the brain. The only exception then was the mind. The mind being nonmaterial did not need to obey the laws of nature and escaped the rules of science and instead resided in the realm of theology. This made dualism an issue of theology versus physics and science for Descartes. These two fields were both very influential on Descartes’ life, and his time period, but were at odds. This provided a solution to this as each focused on one facet of Cartesian dualism and thus has two completely separate content areas. Theology was what

characterized and studied the mind, the existing immaterial souls and spirits, as well as moral and ethical concerns. Physics was then relegated to modeling the physical phenomenon of the material things and there it stayed.

## Interactionism

With Cartesian dualism outlining two completely different types of substances, the problem of how they can coexist and could interact arises as a problem. Humans have both a constant experience of the physical world that has an easier time being objectively characterized and communicated, but we also have a constant experience of our mind as humans doubt and think. The difficulty in accounting for the ability for these two different substances to interact is a vulnerability that drove many thinkers to reject dualism and favor forms of monism instead. Descartes attempts to clarify this ambiguity in the Sixth Meditation of his *Meditations on First Philosophy*. The majority of dualist theories preceding Descartes were unidirectional, stating that the mind, or equivalent immaterial side, was superior to the physical able to overrule its laws and was the origin of our highest abilities. Descartes continued this, privileging the mind as the superior of the two, but thought of them as being able to reciprocally affect each other (Descartes 1641/2007). For example, basic needs not being met for the body, like severe hunger, could start to influence the mind as we lose focus on anything but food. Cartesian dualism clarifies the difference between the brain and the mind with the brain being material and the mind immaterial; functions of the brain could potentially affect the mind. Strong emotions are a function of the brain that could lead the body to overwhelm the rational mind as the emotions affects our behavior and thoughts.

Even with the relationship between the two clarified, the matter of how, and where, these separate substances can interact still had to be addressed. In the *Treatise of Man*, Descartes asserts that the location for this interaction was the pineal gland, a small endocrine gland with the shape of a pine cone that is located near the center

of the human brain (Descartes 1998). What drew Descartes' attention to the pineal gland were mainly false assumptions of the anatomy of the brain, some of which were already disproven in his time. Descartes believed that the pineal gland was held between the ventricles and surrounded by small arteries that brought it the animal spirits aforementioned (Descartes 1998, Figs. 54 and 55). He also thought that the pineal gland is not lateralized at the time it was thought to be one of the few parts of the brain that did not have symmetry across both sides of the brain, and it seemed central. Among his contemporaries, the pineal gland was not thought to have special qualities to give it such an exalted status.

## Implications for Nonhuman Animals

With the cognition of animals already being heavily discredited as anything complex, there was little interest in further research, and Descartes considered them to have no amount of mind. The religious values of the day viewed animals as soulless, lesser beings, and Descartes considered them to be purely constituted by material, physical things. This for Descartes meant animals were not complex enough to think, or doubt, and he even doubted their true ability to feel pain as he thought of them as purely driven by reflexes. His involvement in this topic was a strong push for human chauvinism in regard to comparative cognition and set the stage for centuries of scientific inquiry to work under the presumption that animals were fundamentally lesser. With this, animals were treated like they were inanimate objects, and all rules regarding ethical treatment were thus an unnecessary measure.

## Modern Context

Within the modern world, dualism has fallen into a minority view within academia, with physical monism now being the accepted view for the body of science. Dualism though is still in many ways an intuitive view that holds a lot of attraction to a general audience. Many religious beliefs require a degree of dualism as things that fundamentally

differ from the physical world are purported, such as a soul or any other aspect of a being that is unchanging and carries on beyond a body. There are also many nonreligious discussions that are prone to dualism. For example, complex issues involving the mind such as consciousness tend to have elements that intuitively feel different than something categorically physical, such as what makes humans conscious and how could anything physical create a sensation of experience that we have as conscious being. So while dualism is not normally accepted within the scientific tradition, it is still a prevalent position in modern day. Cartesian dualism is itself rarely believed in an unmodified form and instead is referenced for its historic influence on setting the context for the mind-body problem and modern solutions to it, whether with dualism or monism.

Since Cartesian dualism was first proposed, there have also been many breakthroughs in both the philosophy of mind and science in general that now affect how we view Cartesian dualism and the mind-body problem. Darwin's theory of evolution proposed in *On the Origin of Species* was a huge step in science and profoundly affected Cartesian dualism and the mind-body problem. Evolution links our development as a species to the rest of the living organism that inhabit the planet, undermining the idea that humans are innately superior in terms of mind and intelligence as we are closely related to other animals. This makes the existence of the mind more nuanced than Descartes' conservative stance that nothing but humans existed outside of the physical and reflexes. Advances in neuroscience also stand against much of Descartes' assertions around our neuroanatomy. Our understanding of our nervous system, including the brain, has greatly increased, disproving the idea of a system of nerves full of animal spirits and finding no evidence of the pineal gland being this special point where the mind and body are linked. We have also seen the mind-body problem be addressed in many different ways and recontextualized by philosophers such as Immanuel Kant, Thomas Huxley, and John Searle. Lastly, as the scientific study of consciousness has risen as a field with the works of researchers like David Chalmers who created the

"hard problem" and put the mind-body problem into a new context (Chalmers 1995).

Due to the rapid growth of technology in the modern age, we further have an obscuration of the line between what is mind and what is body. New interfaces are constantly being made that push the limits of our definitions as we develop integration between the organic and the artificial. This is shown with technology like synthesized and mechanical organs, as well as prosthetics that are controlled by our thoughts and neural activity. Examples like the aforementioned have called into question what should be considered part of a person or the environment or part of their mind. With this as well as advancement in the technology, we have to measure the activity of the brain; the mind-body problem naturally had to shift in the modern era in reaction to development in society and science.

## Conclusion

Cartesian dualism revived the Greek debate of monism vs. dualism and brought the focus of dualism away from intellect and toward consciousness setting the stage for the modern mind-body problem. The rise of Cartesian dualism additionally helped give a conceptual structure to the rapid growth of science in Descartes' era as it managed to embrace the laws of physical science and the mechanistic view of humans as constituted by systems with specific purposes. And it still maintained a place for the religious view of the immaterial soul, and superiority of humans over other animals, which characterized his time period. Currently though, Cartesian dualism, and dualism in general in academia, has fallen out of acclaim. The questions brought up by Cartesian dualism concerning what constitutes humans, and what is part of the body and what is part of the mind, continue to be extremely relevant in the modern age.

## Caste

Adam L. Cronin  
Tokyo Metropolitan University, Tokyo, Japan

## Introduction

In group-living organisms, tasks are often partitioned among individuals specializing in

particular roles. Such a division of labor improves the efficiency of task execution and is likely a major benefit of social living. The term “caste” describes the inter-individual differences in behavior (behavioral castes) and, in cases where behavioral roles are associated with different morphology, distinguishes between these physical forms (morphological castes). Morphological castes are typically associated with, and indeed are extensions of, differences in behavior, though differences in behavior need not be associated with differences in morphology.

## Behavioral Castes

Behavioral castes are fundamental to the division of labor in social organisms. This term is typically employed in place of “morphological castes” to describe social groups in which individuals specialize in different roles, such as reproduction or helping, but are otherwise undifferentiated. These individuals are not physiologically constrained to any particular role (i.e., are “totipotent”) and are capable of role switching. Behavioral castes may thus change during an individual’s lifetime, and in many cases roles are age dependent (i.e., temporal polyethism). Behavioral castes (as distinct from morphological castes) are found in many animal societies, including cooperatively breeding vertebrates (both birds and mammals) and social insects which lack morphological castes.

## Morphological Castes

Morphological castes are extensions of behavioral castes, in which specialization of group members on particular tasks is associated with specialized morphology. This phenomenon is distinct from sexual dimorphism resulting from inter- and intra-sexual selection. Morphological castes allow a higher degree of specialization than possible in behavioral castes, as development of unique characteristics and/or modification of existing characteristics allows new tasks to be performed and/or tasks to be performed more efficiently (Oster and Wilson 1978). This specialization comes at a cost to individual

flexibility and totipotency, which can lead to obligate mutual interdependence among castes. For example, queens and workers in many social insects cannot exist independently of one another, as the former are specialized for reproduction and are not capable of many labor tasks, while the latter are modified specifically for labor and may be incapable of reproduction.

Morphological castes are most frequently found in the social insects and have evolved at least 18 times in bees, wasps, and ants (Brady et al. 2006). Morphological castes have also been documented in at least one vertebrate, the naked mole rat, which is unique among vertebrates in having societies which share many characteristics with those of social insects (O’Riain et al. 2000).

In addition to characters directly associated with their particular role, such as enlarged heads and mandibles in soldiers and larger reproductive organs in queens, differences in morphology among group members may also be associated with variation in a suite of physiological and life-history traits, such as disease resistance and longevity. For example, whereas the lifespan of some ant queens can be measured in decades, that of workers of the same species may be measured in weeks (Hölldobler and Wilson 1990).

## Diversity of Morphological Castes

Morphological castes exist in their most fundamental form as part of the reproductive division of labor in societies in which one caste (queens) specializes in reproduction while the other (workers) undertakes nonreproductive tasks. In most social insects, the reproductive caste is larger than the worker caste, and species with larger colonies tend to exhibit a higher degree of caste dimorphism. This differentiation can exceed two orders of magnitude, though the degree of caste differentiation varies considerably between species and depends on a number of life-history traits (Hölldobler and Wilson 2009). Dimorphism is also greater in the ants than in bees or wasps, almost certainly because the loss of flight in the former has removed limitations on the evolution

of more diverse characteristics (Peeters and Ito 2015).

Reproductive castes are, unsurprisingly, specialized for reproduction. In extreme cases in social insects, this can include morphological specializations such as physogastry (distension of the abdomen to accommodate larger reproductive organs at the cost of mobility). Such females are effectively “egg-laying machines” and the rate of egg production in some species can reach tens of thousands per day (Gotwald 1995). These females are otherwise largely helpless, however, and must be tended by workers. Reproductive castes may also exhibit specialized traits for dispersal. New colonies are initiated by newly emerged and mated queens, and in many ant species it is only the queens (and males) that are winged. These ant queens accordingly possess enlarged thoraces to house large flight muscles, and have larger eyes than those found in workers.

Worker castes instead have traits suitable for labor tasks and typically have reduced reproductive capacity or may lack reproductive organs altogether (and be completely sterile). Workers perform the bulk of the labor tasks and thus undertake the greatest diversity of roles in the colony. In some groups, labor tasks are performed by morphologically distinct worker forms. For example, the leaf-cutter ant species *Atta sexdens* has four morphologically distinct castes: gardener-nurses, within-nest specialists, forager-excavators, and soldiers (Wilson 1980). Defense of the colony is critical for social insects, and specialized fighting castes (soldiers) exist in a range of ants, thrips, and termites. Soldiers may have enlarged and/or specially shaped mandibles and enlarged heads to house the associated musculature. Alternatively, morphological adaptations may be entirely defensive: in turtle ants, specialized soldier castes use their plate-like heads to block the entrance to the nest, effectively making them “living doors.” In other ant species, more unusual worker castes with highly specialized functions have evolved in response to strong environmental pressures. In several arid-zone species, for example, workers called “repletes” function as specialized living storage organs and have expanded abdomens in which they retain liquid food for the colony.

## Basis of Morphological Caste Formation

Morphological castes are formed via differential growth of different parts of the body during development into adults (i.e., allometry; Hölldobler and Wilson 1990; Oster and Wilson 1978). Different castes can arise in this manner from the same genotype though variation in environmental factors such as nutrition or social context. For example, the feeding of “royal jelly” helps push developing larvae into the path leading to the queen caste in honey bees. On the other hand, queen development in various social insect species is suppressed by the presence of a fertile queen in the nest via pheromonally mediated feedback loops. Recent evidence suggests that these environmentally induced effects on caste development are likely to function via their influence on the process of DNA methylation (Weiner and Toth 2012). In other cases, caste formation is partially or entirely determined by genetic differences between castes, and current evidence suggests that the degree to which environmental and genetic factors contribute to the development of different castes varies considerably between species (Schwander et al. 2010).

## Definition

A comparison of cognitive abilities within the primate parvorder Catarrhini (Old World monkeys, gibbons, and great apes).

## Introduction

The catarrhine primates include Old World monkeys (family Cercopithecidae), gibbons (family Hylobatidae), and great apes (family Hominidae, including humans, chimpanzees, bonobos, gorillas, and orangutans; Perelman et al. 2011). Old World monkeys account for an estimated 40% of extant primate genera; however, the phylogenetic relationships of some species are highly debated. The family is broken up into two subfamilies, Cercopithecinae (12 genera) and Colobinae (10 genera; Perelman et al. 2011). Gibbons (small apes) diverged between Old World monkeys and great apes. The family divides into four genera with 12 extant species, although the phylogenetic relationship between species is also controversial (Takacs et al. 2005).

The comparison of Old World monkeys, gibbons, and great apes provides the opportunity for a unique comparison of cognitive abilities between three evolutionarily diverged species. Here we will review cognitive processes of species within these families, with an emphasis on concepts and categorization, tool use, memory, self-awareness, and social cognition. Due to the large volume of species included in Catarrhini, we will focus specifically on key similarities or notable differences within each topic. A thorough review of primate cognition and its subcategories is well documented in published literature (for full reviews on primate cognition, see Deaner et al. 2006; Tomasello and Call 1997; and Washburn 2007). A discussion of communication within Catarrhini is found in a separate entry in this volume, and will not be covered here. Additionally, cognition in humans (*Homo sapiens*) will not be included in this entry.

## Primate Cognition

Cognition is multifaceted, integrating perception, learning, memory, and decision-making. Essentially, it is the process of sensing and processing information about the world, remembering that information, and deciding to act on it (Shettleworth 2001). Comparisons between primate species on this and other cognitive traits are problematic due to the highly variable research methodologies across studies. Even when researchers employ identical or similar methodologies, interspecific differences in motivation and perception may influence performance. Additionally, the majority of published studies in primate cognition have small sample sizes, making it difficult to ascertain true statistically significant differences between species.

Meta-analyses indicate that certain species perform at higher levels on specific cognitive tasks, although in other tasks there are no significant differences observed between species (Deaner et al. 2006). Current research suggests that great apes are superior to gibbons and Old World monkeys in formal cognitive tasks and in measures of intelligence extracted through principal components analysis (Reader et al. 2011). Phylogenetically, it is reasonable to expect that gibbons would outperform Old World monkeys in these tests; however, in many cases they perform inferiorly to monkeys in formal testing situations. However, note that cognitive tests of gibbons are less common than other catarrhines, and additional research is essential for a full understanding of their cognitive abilities. Recent genetic analysis suggests that multiple evolutionary events influenced the development of intelligence across primate lineages; in catarrhines, pronounced differences in independent responses to selection were evident in baboons, macaques, and the apes (Reader et al. 2011).

## Concepts and Categorization

Two fundamental aspects of cognitive abilities include the formation of concepts and the capacity

to discriminate and/or generalize environmental stimuli into meaningful categories. There is no standard operational definition for identifying concept formation in nonhuman animals, although most researchers agree that the creation of a concept involves the perception and classification of objects or events into physical or relational classes using explicit response rules. Current research suggests that Old World monkeys are distinguishably inferior to apes in their capacity to conceptualize. In this section, we will specifically look at species comparisons for object permanence, conservation, and discrimination.

Object permanence is the understanding that an object continues to exist, even when out of sight. Apes and macaques are able to perform this Piagetian developmental task and have shown evidence of creating perceptual categories during test administration. Gorillas, chimpanzees, and orangutans all reach Stage 6 of the object permanence task, although only gorillas have demonstrated an ability to understand non-adjacent displacements. Macaques do well on visible displacement tests, but do not perform above chance levels on invisible displacement tests. Research on object permanence in gibbons is limited, but suggests that they have abilities similar to those of the great apes (see Fedor et al. 2008, for a review).

Piagetian conservation involves the ability to understand that the physical properties of an object remain the same despite changes in the perception of the object. Great apes appear to possess this ability for discrete quantities and continuous quantities, but with species differences. Bonobos succeed significantly more with discrete quantity tasks; chimpanzees perform better with continuous tasks; orangutans are equally successful with both types. Additional research also indicates that gorillas are capable of relative quantity discrimination of whole sets of stimuli, performing at equal levels to the other three non-human great ape species (Hanus and Call 2007). Limited research on Old World monkeys and gibbons exists; rhesus macaques are successful in the task, though they are not as proficient as the great apes (Beran 2007).

Discrimination studies in nonhuman animals may take several forms, including same/different discrimination tasks, match-to-sample tasks, and stimulus response measures. Stimuli presentations may be visual, auditory, tactile, or olfactory. Interspecific and even interstudy comparisons are problematic due to the vast number of potentially confounding variables. For example, previous experience as well as the type of trials, rewards, and methodologies used affect animal performance (Deaner et al. 2006). Comparative discrimination studies involving all three subfamilies of catarrhine are extremely limited. However, recent meta-analysis found that macaques, gorillas, and chimpanzees performed equally well on object discriminatory tasks, superior to the performance of both gibbons and orangutans (Deaner et al. 2006). Macaques and baboons perform significantly above chance in quantity discrimination learning and do not show significant variation from chimpanzees and orangutans (Schmitt et al. 2012). Additionally, object discrimination reversal learning research suggests that chimpanzees and gorillas exceed the abilities of orangutans, which score higher than macaques. Cercopithecines outperformed gibbons in this particular meta-analysis. Delayed response tasks also demonstrate interspecific differences, ranking from highest to lowest as follows: orangutans, baboons, mandrills, gibbons and macaques, and cercopithecines (see Deaner et al. 2006, for a full review).

## Tool Use

The use of tools in both wild and captive settings involves several aspects of cognition, including causality and representation. Tool use requires the individual to understand how the manipulation of the object will affect another object. Great apes and macaques are the only catarrhines with known widespread tool use in the wild; this may be a reflection of manual dexterity as well as imitation skills and gregariousness, suggesting that social cognition and intelligence play a large role in the development of this skill (Gumert et al. 2011). Studies of tool use in gibbons are lacking, although reviews can be found in Cunningham

et al. (2016). In general, gibbons demonstrate less innovative tool use than macaques, which is surprising given their phylogenetic position in the parvorder.

Chimpanzees use tools for extractive foraging and often begin early in development. They tend to have higher rates of object manipulation and more diversity in those manipulations in comparison to bonobos, gorillas, and orangutans, with gorillas demonstrating the least amount of tool use in both wild and captive settings (Meulman and van Schaik 2013). Chimpanzees also demonstrate observational learning and cultural transmission of tool use, and may even save tools for future use (Mulcahy and Call 2006). Use of tools in primates may be related to enculturation; for example, orangutans and bonobos rarely use tools in wild populations, but are frequently observed using tools in captive or rehabilitative contexts (Furuichi et al. 2015; Meulman and van Schaik 2013). Additionally, social structure may play a large role in tool use, with more gregarious species such as chimpanzees showing higher levels of social learning compared to less social species such as the orangutans (Meulman and van Schaik 2013). However, as mentioned by Furuichi et al. (2015), these observed species differences might not be related to cognitive abilities; rather, they may be indicative of divergent behavioral predispositions. In captive groups, bonobos engage more frequently in playful behaviors with tools compared to chimpanzees, and this may reflect an inherent preference for this type of behavior. See Gruber and Clay (2016) for a full review of chimpanzees and bonobos.

## Memory

The cognitive process of memory provides an individual animal the opportunity to adjust their behavior based on past experience (Shettleworth 2001). Memory divides into several subtypes, including episodic memory (memory of personally experienced life events), spatial memory (environmental orientation), and prospective memory (forming intentions). Within the catarrhines, the majority of memory research has been conducted with the great apes.

Chimpanzees, bonobos, and gorillas demonstrate evidence of episodic-like memory, which is hypothesized to relate to social relationship formation (Schwartz and Evans 2001). Both chimpanzees and orangutans have shown aptitude for remembering episodic components of a task after a delay of 3 years (Martin-Ordas et al. 2013), and chimpanzees show spontaneous memory retrieval without prompt (Schwartz and Evans 2001). Spatial memory is important for primate foraging behavior. The development of spatial memory may be a reflection of ecological pressures; that is, chimpanzees, which have a more distributed food availability, prefer to incorporate spatial strategies when solving a memory foraging task. Bonobos, in contrast, have more continuous food access and therefore lack the more sophisticated spatial memory seen in chimpanzees (Rosati and Hare 2012). In terms of prospective memory, chimpanzees demonstrate the ability to encode information, retain that information for an extended period, and then implement the recalled information for a reward (Beran et al. 2016).

Limited research is available on the study of memory in gibbons and Old World monkeys, with the exception of rhesus macaques. Awareness of memory has been a topic of particular interest within this species, and individuals have exhibited episodic-like aspects of memory in foraging tasks (Hampton et al. 2005). Experimental evidence suggests that macaques are capable of reporting whether or not they remember an answer and are adept at memory maintenance (Basile and Hampton 2013). Note that memory studies in any nonhuman animal may have several alternative explanations, and additional research and debate is needed for a more complete understanding and interspecific comparison.

## Self-Awareness and Social Cognition

The study of animal cognition is often criticized by the sometimes-anthropomorphic nature of its methodology. However, some authors believe that anthropomorphism may be useful in creating testable hypotheses. The majority of these relate to emotional attributes rather than cognitive states. Human terms of cognitive states cannot be

attributed to mental processes in animals in which subjective feelings are projected onto another individual, such as the belief that a predator is dangerous. However, it is possible to interpret an animal as *wanting* another individual to believe something, as in the case of deception. Perhaps monkeys and apes are able to engage in deceptive and manipulative behaviors by monitoring conspecifics and identifying their intentions (Whiten 2013).

The question of whether nonhuman primates possess a human-like theory of mind, in which they can attribute separate mental states to others, is highly debated. In general, monkey and apes demonstrate the fundamental components of theory of mind, including gaze-following and understanding intentions (Platt et al. 2016). Chimpanzees, for example, can follow gaze, but it is unknown whether they can infer the experimenter's mental state related to the gaze. Macaques and sooty mangabeys are also adept at gaze-following, although succeed better at the task when the gaze is provided by a conspecific (Meunier 2016). In terms of understanding the intents and goals of another individual, chimpanzees appear to be able to distinguish between purposeful and accidental behavior (Seed and Tomasello 2010), and it is reasonable to assume that the other great apes share this ability. Rhesus macaques also demonstrate the ability to infer goals, although additional replication studies are needed to confirm this finding (Meunier 2016). Cognitive ability plays a large role in the ability to form adaptive social bonds and understand the intentions of other members in the social group; therefore, it is not surprising that catarrhines show evidence of these traits.

Social living may come at a great cost to individuals. For example, large groups are more conspicuous to predators, and diseases and parasites spread quickly. There is greater competition for food, and subordinate males expend more energy in dealing with dominant group members. Alternatively, large groups have a greater defense against predators and assistance is readily available from others for dealing with pathogens. Foraging improves due to information sharing, and subordinates are provided the safety of the group (Alcock 2009). In Old World monkeys,

females form long-term, stable relationships and engage in affiliative behaviors such as grooming. These close social bonds provide more protection while sleeping or feeding and prevent the loss of offspring. Furthermore, females with strong social bonds cope with stress more efficiently, as measured by levels of stress hormones; this also benefits offspring, as high stress levels are harmful to their health and behavior. Therefore, cooperative social bonds likely have a strong influence on individual fitness, even in the absence of competitive advantages such as ally support and dominance rank (Platt et al. 2016).

One of the most significant inquiries in the field of comparative psychology is the question of self-awareness in nonhuman animals. The cognitive ability most related to this feature of consciousness is that of self-recognition. Mirror Self-Recognition (MSR) tasks have been investigated with several species of catarrhines across all three families. Chimpanzees, bonobos, and orangutans all demonstrate MSR abilities, although social exposure is an important component for development. MSR in gorillas is less obvious, with a few individuals testing positive for the ability while others fail. No gibbons or Old World monkeys have been successful in an MSR task to date. Monkeys may respond socially to a mirror, but do not show self-directed behaviors. For a full review of MSR in primates, see Anderson and Gallup (2015).

## Conclusion

Although the study of cognition in primates dates back several decades, only recently have interspecific comparisons become an area of high interest. The catarrhines provide a unique opportunity for a phylogenetic comparison of cognitive abilities due to the divergent branching of their evolutionary history. The great apes (particularly chimpanzees) and macaques have a disproportionate amount of research compared to gibbons and other Old World monkeys. The future of the field holds many exciting possibilities for the understanding of primate cognition.

## Catarrhine Communication

Marlen Fröhlich  
Anthropological Institute and Museum,  
University of Zurich, Zurich, Switzerland

## Synonyms

Apes; Audition; Facial expression; Gesture; Modality; Multimodal; Old world monkeys; Olfaction; Sensory channel; Signal; Touch; Vocalization; Vision

## Definition

Old world monkeys and apes exhibit a large array of visual, acoustic, tactile, and olfactory signals.

## Introduction

Communication presents the foundation for all social behavior of primates, and the need to navigate their complex social environments has contributed to the evolution of sophisticated communication systems (Semple and Higham 2013). This entry provides an overview of communication patterns identified in catarrhines, a primate clade constituting two superfamilies: Cercopithecoidea (old world monkeys) and Hominoidea (apes). Catarrhines are distinguished from other primates by downward-facing nostrils, opposable thumbs, and a reduced vomeronasal organ, among numerous other traits. Species of this taxon are generally diurnal, live mostly in social groups, and exhibit extended

periods of maternal care; characteristics that are thought to have important implications for the evolution of their communicative systems. Catarrhines communicate with conspecifics to solve problems of survival (e.g., predation and defense of food sources), reproduction (e.g., sexual behavior and mother-offspring coordination), and group living (e.g., alliance formation and conflict resolution) (Liebal et al. 2013).

Given the immense variety regarding definitions of communication in the literature, it should be first clarified what this entry considers as a “signal”. Following the “influence” concept of communication, signals represent traits that exert influence on other individuals through sensory stimulation, and have been under selection specifically for their communicative function (Higham and Hebets 2013). In recent years, the communication of catarrhines tended to be mainly divided into three behavioral modalities – gesture, facial expression, and vocalization – encompassing the sensory channels of vision, touch, and audition (Liebal et al. 2013). The comparative research on ape and monkey communicative behavior has been widely used to trace the evolutionary roots of language, often focusing on underlying cognitive abilities such as intentionality and reference (Arbib et al. 2008). Owing to this comparative bias, most reviews of primate communication focused on behavioral signals only, with communication defined based on assumptions about potential underlying cognitive mechanisms rather than evolutionary function. Defining communication as involving behavior on the signaler’s behalf results in the neglect of other important signal types in definitions, such as genital swellings and the bright facial colors of the mandrill *Mandrillus sphinx*. Moreover, the conceptual focus on signal production and form rather than signal perception and function (Semple and Higham 2013) meant that the visual sensory channel has often been treated as two modalities of “gesture” and “facial expression” (Fröhlich 2017). However, to understand the function of animal signals, it is vital to consider the role of receiver perception and thus the receiver’s sensory systems that are stimulated (Higham and Hebets 2013). This

entry will follow the suggestion of Semple and Higham (2013) and present communication in terms of sensory modalities through which signals are perceived by the recipient, but also with regard to production and the different forms in which they are produced by the signaler.

Catarrhine primates produce and perceive signals in multiple sensory modalities, including the visual, acoustic, tactile, and olfactory channel, which differ in precision with regard to intended receivers (“locatability”), range, and persistence over time (“fade-out time”). Thus, the usage of different sensory modalities is constrained by features of the physical and social environment. In arboreal and densely vegetated settings, visual signals like facial expressions and gestures are transmitted less effectively and are thought to play a less important role than acoustic signals, especially if opportunities for close-range interactions among conspecifics are limited. While we would not expect a large repertoire of visual signals, these environments may favor the evolution of a complex vocal repertoire (Marler 1965). Since catarrhine primates are commonly diurnal, most close-range communication is visual, whereas long-range communication is predominantly audible. Moreover, the social structure and mating system profoundly influences communicative interactions within a species. Primates vary enormously in the complexity of their vocal, visual, and olfactory signaling repertoires, and the hypothesis that social complexity is linked to communicative complexity (Freeberg et al. 2012) has gained popularity among primatologists in recent years. While there is some evidence that group size in primates is positively correlated with both facial and vocal repertoire (Liebal et al. 2013), these findings should be viewed with caution given that signals are often highly graded, and researchers seldom agree on how to classify repertoires (Semple and Higham 2013). Nonetheless, sociality is supposed to favor the communication via multiple channels, as the interacting animals are spatially close enough to see, hear, smell, and/or touch each other. Multimodal signals may thus be especially suitable for short-distance communication, which is prevalent in many group-living

species of the primate order (Marler 1965). Although this entry introduces communication in the sensory modalities of vision, audition, touch, and olfaction separately, it is important to recognize that primates produce and perceive signals rarely in a unimodal format. As outlined below (section “Multimodal Use of Signals”), the simultaneous and sequential organization of signal elements must be considered to decipher complex signal function.

## Visual Communication

Catarrhines rely heavily on visual information, and the role of vision in primates’ neural and sociocognitive specialization has been emphasized by several comparative studies. In particular, primates’ elaborated visual system has evolved towards high visual acuity compared to most other mammals (Liebal et al. 2013). Catarrhines have evolved a comparably high level of orbital convergence (i.e., eyes facing in the same direction, namely forward), which resulted in binocular visual fields enabling stereotypic vision. Accordingly, the variety of visual signal types is very large, spanning from sexually selected signals like morphological swellings to behavioral signals such as gestures and facial expressions. The main benefits of the visual channel are fast transmission rates, short fade-out times, and the rapid locatability of the sender. Visual signals like facial expressions and piloerection tend to be effectively perceived only at close proximity to the signaler, but their precision makes them exceptionally suitable for dyadic, close-distance communication.

### Skin Coloration and Swellings

The evolution of uniform trichromatic vision in catarrhines seems to have led to a variety of red skin signals. An extraordinary example of visual communication is presented by the case of mandrill face coloration: males were shown to use the rank-dependent brightness of another male’s red coloration to assess individual differences in fighting ability (Setchell and Jean Wickings 2005).

Further research on the perception of the facial blue-red contrast suggested that the multicolored face of mandrills represents a multicomponent signal perceived within the same sensory channel (Renoult et al. 2011).

During specific phases of the ovarian cycle, females of numerous catarrhine species exhibit conspicuous swellings of the perineal skin. These hormone-dependent sexual signals are among the largest and the most colorful signals exhibited by any mammal. The exaggerated size of swellings has caused many evolutionary biologists to speculate that sexual selection has strongly influenced their evolution. With respect to signal function, the best-supported theory is probably Nunn’s (1999) “graded-signal hypothesis”, stating that sexual swelling size contains information about the intra-individual likelihood of ovulation. In this probabilistic model, swellings are larger when the likelihood of ovulation is greater within a cycle. However, the study of swellings has rarely been expanded beyond the element of swelling size. Since mate choice theory poses that males are likely to use multiple signal components of sexual signals, recent studies have emphasized that other visual elements, such as color, shape, and symmetry might also play a role in mate choice. For instance, size of female sexual swellings in female olive baboons *Papio anubis* may facilitate to assess fertility and parity of the signaler, whereas color was shown to be related to parity only (Higham et al. 2008).

### Facial Expression

Catarrhines have a remarkable facial mobility, and most species employ specific facial expressions through movements of the jaws, lips, ears, eyelids, and other facial features. Facial expressions have been commonly assumed to be expressions of emotional states that are largely innate and involuntarily produced (Tomasello 2008). While frequently studied as emotional displays, research has also considered them as true signals, evolved to allow receivers to predict the behavior of senders and to allow senders to manipulate receivers (Waller and Micheletta 2013). Some expressions, like the bared-teeth display, are

shared universally among the primate order. The precise meaning and context of the bared-teeth expression can vary between species, but it has long been argued that these similar expressions, including the human smile, comprise homologous traits (van Hooff 1972). Likewise, relaxed open mouth displays are frequently found in the repertoires of different primate species, usually associated with play, and thought to be homologous with human laughter (van Hooff 1972) and playful open mouth expressions seen in other mammals, such as dogs, bears, and even rats (Waller and Micheletta 2013). Facial expressions have been suggested to serve as “meta-communicative” devices to clarify the meaning of ambiguous, potentially agonistic behavior. For example, great apes frequently produce a “play face” when approaching others for play solicitation, presumably to assure that a hitting gesture or wrestling is perceived as intention to play and not as an aggressive approach (Rijksen 1978).

Some facial expressions are less ubiquitous and are only found in specific species or taxa. The “lip-smack” expression, for example, is a dynamic display that involves the fast-paced rapid closing and opening of the mouth and lips (Ghazanfar et al. 2012). Mainly associated with affiliative behaviors (e.g., social grooming) and suggested to facilitate tolerance, it is observed in many old world monkeys, particularly macaques and baboons (Van Hooff 1967). These species often produce lip-smacks during friendly approaches or face-to-face greetings, as well as during mother-infant interactions. While lip-smacking is a multimodal signal with both an audible and a visual element, the visual component has been shown to be sufficient in rhesus macaques to elicit reciprocation of this signal. Recent studies have highlighted the role “lip-smacking” facial expressions might play for understanding of language precursors, proposing that rhythmic facial movements required for speech production evolved from facial movement patterns in a primate ancestor (Ghazanfar et al. 2012). This theory is based on evidence that the temporal pattern and developmental trajectory of “lip-smacking” (starting with a variable “babbling” phase) in rhesus macaques resembles the timing and ontogeny of speech.

## Visual Gestures

Gestures have been defined as socially directed, mechanically ineffective movements of the extremities, head or body, as well as body postures that exert influence on another individual without coercion (Call and Tomasello 2007). Unlike research on human gesture, which usually focuses on the visual channel, research on primate gestures involves three sensory channels, since gestures can be perceived visually, tactilely, and/or acoustically. Gestural studies, mainly conducted in captive settings, have firmly established that old world monkeys and great apes frequently use visual gestures in their natural intraspecific communication. Visual manual and bodily signals are used in a wide range of social contexts (Call and Tomasello 2007) and are often accompanied by context-dependent facial expressions and postures: For instance, begging gestures solicit food transfers, beckoning gestures initiate sex and submissive gestures (e.g., presenting hindquarters) signal subordination towards a threatening dominant male. Male hamadryas baboons, *Papio hamadryas*, use various visual gestures to coordinate group movement and negotiate travel direction: the so-called notifying behavior involves an “approach – turn body – present hindquarters – look back” sequence, and group travel is initiated often by a male setting off in his preferred direction with a purposeful gait (Fischer and Zinner 2011).

Primates’ employment of visual gestures has often been used to infer whether a particular signal is used in a goal-directed (“intentional”) way. Communicating more/only via visual gestures only when the audience is visually attending and thus receptive to the signal suggests that the sender has an intention to manipulate the receiver’s behavior (Liebal et al. 2013). Recent studies on the gestural development in wild chimpanzee infants suggested that visual gestures increase at the expense of tactile signals with decreasing mother-infant proximity and increasing interaction rates with nonmaternal conspecifics (Fröhlich et al. 2016b). Numerous lines of comparative research suggested that nonhuman primates have considerably more intentional control, flexibility, and interactional awareness of

their productive gestural communication than of their vocalizations or facial expressions (Arbib et al. 2008; Tomasello 2008). With accumulating evidence for flexible and goal-directed use of vocalizations and facial expressions, this view has however been alleviated in recent years.

## Acoustic Communication

Sound plays a crucial role for maintaining group cohesion, allowing for long-distance communication with spatially disparate group members in dark and/or densely vegetated environments where opportunities for visual communication are limited. Compared to visual and tactile communication, acoustic signals are seldom targeted precisely at specific receivers, and broadcasted rather indiscriminately. While vocalizations are the most common form of acoustic communication, communication through sound does not always involve the vocal folds: auditory gestures and unvoiced calls are other acoustic communicative means employed by several catarrhine species.

## Vocalizations

Vocalizations are defined as utterances resulting from vibrations of the vocal folds within the larynx, which can exhibit a large variation in acoustic structure. The production of a vocalization involves air expulsion from the lungs, resulting in rhythmic opening and closing of the vocal folds that can be perceived as sound waves. Frequency, amplitude, and temporal pattern can differ according to recipient and physical environment. With the benefit of traveling large distances, vocalizations function to defend territories and food resources, and to locate conspecifics. Within a social group, vocalizations are produced in contexts like foraging, travel, copulation, and aggression. Research on contact call function in foraging primate troops has revealed that call rate increases with the distance to the nearest neighbor and habitat density (Bradbury and Vehrencamp 1998). With increasing separation distance, Japanese macaques, *Macaca fuscata*, may increase call duration, amplitude, and frequency modulation to enable the reunion with group mates (Koda

2004). Several catarrhine species rely on vocalizations as consensus-building departure signals to coordinate group travel: in mountain gorillas *Gorilla beringei beringei* and chacma baboons *Papio ursinus* several individuals increase the production of grunts before the initiation of travel (Fischer and Zinner 2011), whereas in chimpanzees (*Pan troglodytes*) only particular individuals produce “travel hoos” that seem to be directed at closely bonded individuals (Gruber and Zuberbühler 2013). Social intragroup calls are often not broadcast indiscriminately, but affected by identity and dominance rank of the receivers. Rhesus macaques, *Macaca mulatta*, were shown to give five acoustically different “screams” when interacting with opponents varying in rank, relatedness etc., which elicited different responses from group mates depending on opponent type and agonistic situation (Gouzoules et al. 1984).

While primates’ intragroup calls generally exhibit a lower amplitude and higher acoustic variation, intergroup calls often travel long distances through the environment. Territorial “loud calls”, as produced by gibbons, are thought to function to announce the location of the caller within the territory and to repel other individual and groups. Predator-specific alarm calls are another class of “loud calls”, which can address the predator and close-by group members (Zuberbühler 2001). It has been argued that alarm calls of several catarrhine species qualify as “functionally referential”, that is, they are correlated with the occurrence of objects or events in the external world of the signaler, and induce the receiver to respond adaptively in the absence of direct cues from the eliciting stimulus. This context-sensitive semanticity has been demonstrated for several species of old world monkeys, with individuals responding to acoustically distinct calls with particular types of antipredator responses even in the absence of the predator. For instance, vervet monkeys *Chlorocebus pygerythrus*, Diana monkeys *Cercopithecus diana*, and Campbell’s monkeys *Cercopithecus campbelli* all use distinct alarm calls for different predators, eliciting appropriate escape responses in other group members (Zuberbühler 2001).

Vocal turn-taking, defined as coordination of vocal contributions by two individuals, has been evidenced in Campbell's monkeys (Lemasson et al. 2011), and from the lesser apes, siamangs *Hylobates syndactylus* (Geissmann and Orgeldinger 2000). In siamangs, pair-bonded males and females produce loud and ritualized "duetting" vocalizations for territorial defense, but also to strengthen existing pair bonds or to attract new mates (Geissmann and Orgeldinger 2000). Reports of vocal turn-taking in the great apes are limited to reports of male chimpanzees chorusing with pant-hoots, an acoustically distinct long-distance call. Chorusing in male chimpanzees seems to reliably reflect short-term affiliation, facilitating feeding tolerance and predicting support in agonistic interactions (Fedurek et al. 2013).

### Unvoiced Calls

Sounds produced with the mouth but not involving the vocal tract have been termed unvoiced or voiceless calls and include "kiss squeaks", "raspberries", "whistles", and "lip-smacks" (see section "[Facial Expression](#)"). The kiss squeak is produced by a sharp intake of air through pursed lips and has been demonstrated to serve as alarm call in wild Bornean, *Pongo pygmaeus*, and Sumatran orangutans, *Pongo abelii*, in response to encounters with potential predators or conspecifics (Rijksen 1978). In some populations, the "kiss squeak" is performed by positioning a hand or a hand with leaves in front of or against the lips during production (van Schaik et al. 2003). "Raspberries" are spluttering sounds that are produced by orangutans of some wild populations during nest building (van Schaik et al. 2003) and by captive chimpanzees as attention-getting sounds towards their human caretakers (Liebal et al. 2013). Orangutans have been shown to copy "whistling" sounds from humans, demonstrating the ability to acquire a novel voiceless call belonging to a repertoire of a different species. However, although human-ape experimental setups have the potential to reveal apes' cognitive abilities, they cannot provide insight into strategies that are employed in their natural communication with conspecifics (Liebal et al. 2013).

### Auditory Gestures

The most popular example of a gesture producing sound is probably the gorillas' "chest-beat", which is used as part of their display behavior or to invite others to play. Many of the reported auditory gestures in great apes (e.g., "clip leaf" and "slap object") have been suggested to serve as "attention-getting" signals that do not convey specific information about the context. The signaler's message might be rather conveyed in the context-typical facial expressions (e.g., "play-face") or body postures (Tomasello et al. 1994; however, see Liebal et al. (2013) for different view). Most gestures producing a sound element are actually considered audio-visual gestures, as they normally also have salient visual components. Hence, the visual orientation ("attentional state") of the recipient must always be assessed to infer which components of a signal were salient for perception (Fröhlich 2017). Adult chimpanzees and bonobos are commonly observed to drum on the trunks of trees, by beating their hands and feet against on the hard surface. Drumming by chimpanzees, often accompanied by "pant-hoot" vocalizations, is performed in multiple contexts including traveling, display, inter-group encounter, and when arriving at large food sources (Crockford and Boesch 2005).

### Tactile Communication

Tactile signals, similar to visual signals, enable rapid and precise communication particularly suitable for dyadic, close-distance communication. Out of the four communicative modalities presented, tactile signaling is arguably the most intimate and risky, since it is the only one that requires the renunciation of individual space and, in many cases, the exposition of vulnerable body parts. Surprisingly, touch is often neglected as a communicative channel in reviews of primate communication. Primates rely on tactile signals to resolve conflicts, mediate courtship, reaffirm affiliative and dominance relationships, and coordinate group movements. Tactile appeasement tactics and signals are of particular importance for maintaining peace in groups, involving post-conflict

reconciliation, third-party consolation, allogrooming, and greeting displays (Bradbury and Vehrencamp 1998). Reconciliation acts following conflicts frequently involve close contact, particularly the winner approaching and embracing, kissing, or grooming the loser. Chimpanzees are thought to reconcile particularly often after conflicts, but this behavior is also reported for old world monkeys like macaques and baboons. Consolation behavior after conflicts, usually by a closely bonded individual not involved in the conflict, involves embracing, grooming, and other types of touch such as licking and genito-genital rubbing. Third-party consolation is observed in chimpanzees and bonobos but less frequently in old world monkeys (Bradbury and Vehrencamp 1998). Both reconciliation and consolation serve to decrease the occurrence of anxiety behaviors in the victim through comforting or reassuring. Allogrooming, the grooming of another individual, is a universal behavior and probably the most widespread interaction involving touch in catarrhine primates. While one obvious function of this behavior is the removal of parasites and debris from the body surface of the groomed animal, it also serves to reaffirm affiliative bonds or the relative dominance status between groomer and groomee. As a major tension-reducing strategy in primates, allogrooming can be exchanged for other “goods” such as mating opportunities, tolerance, or agonistic support in future conflicts. Allogrooming has a crucial communicative function, as the act of grooming carries the message that the recipient is considered a valuable social partner, which can be used to infer the partner’s willingness to support each other in high-risk collaborations. It is most commonly observed between related group members, within female matrilineal groups among old world monkeys and among males in chimpanzees, but also beyond kin relationships. In several catarrhine species, individuals greet the arrival of a known conspecific with physical contact, such as when baboon males touch each other’s genitalia, chimpanzees clasp the partner with one arm in a loose embrace, or bonobos engage in mutual genital rubbing.

Tactile gestures can be distinguished from mere physical actions in that they are not

mechanically effective (i.e., they do not function through coercion) and communicate a specific intent. For example, gently touching an individual’s back during a grooming session to indicate a desire for that individual to lie down would be a tactile gesture, as opposed to the direct physical action of forcefully pushing the other to the ground. Tactile gestures are particularly common in affiliative contexts like grooming and reassurance. A recent study on play-soliciting signals in immature chimpanzees found that infants used tactile gestures predominantly in interactions with their mothers, with whom predictable outcomes and high familiarity have been established in many previous interactions (Fröhlich et al.).

## Olfactory Communication

Chemical signals, perceived using olfaction, provide the advantage of persisting over time but lack precision with regard to receivers. Old world monkeys, apes, and humans have traditionally been considered as “microsmatic”, with decreased reliance on olfactory senses in comparison to other sensory modalities such as vision. The olfactory system of catarrhines is thought to be considerably less complex than in prosimians and new world monkeys, as accessory olfactory bulbs (AOBs) are lacking and the vomeronasal organ is markedly reduced (Barton 2006). The majority of evidence for olfactory communication in primates, such as scent and urine marking, stems from prosimians and callitrichids. These taxa possess numerous scent glands producing secretions containing so-called pheromones, substances secreted by an animal with specific effects on the behavior or physiology of conspecific.

However, the importance of olfactory communication in catarrhines has been increasingly recognized in recent years (Vaglio et al. 2016). Odor and the main olfactory system are thought to be involved in sexual and social behaviors, and specifically the attraction of males to estrous females (Barton 2006). Observational studies suggested that pheromones play a critical role in the sexual context, as olfactory inspection (“sniffing”) by male catarrhine primates is commonly observed.

Sternal-gland secretions in mandrills have been shown to signal sex, age, male dominance, and possibly individual identity and group membership, suggesting that scent-marking serves territorial functions but also sociosexual functions of communication in this species (Vaglio et al. 2016). Chimpanzee males show an intensified interest in copulation around the period of female ovulation, which has been related to their ability to detect olfactory signals produced by the female at the time of ovulation. A few studies suggest that vaginal secretions during estrus of female chimpanzees contain pheromones that signal reproductive capacity and physiological status. While chimpanzee females produce a mix of volatile fatty acids in vaginal secretions, only isobutyric acid increases during the ovulation period, which might affect male sexual responsiveness (Matsumoto-Oda et al. 2003). However, as the females of many primate species develop sexual swellings varying in shape, size, and color (see section “[Skin Coloration and Swellings](#)”), and thereby multicomponent signal of two sensory modalities, it is important to disentangle how these different signal components contribute to male responses.

### Multimodal Use of Signals

Communications systems of primates are intrinsically multimodal, often involving a simultaneous and sequential production of different signal components in multiple sensory channels. In fact, research on catarrhine communication at both the behavioral and neuronal level has demonstrated a widespread capacity to flexibly combine signals from different modalities (Liebal et al. 2013). A vivid example for a complex communicative scenario was described by Higham and Hebets (2013) for the context of sexual behavior: “[...] male baboons are highly aroused by the visual signal of female sexual swellings (which themselves vary in multiple components such as size, shape, symmetry, and colour), which they then touch (possibly to assess how inflated the swelling is), before sniffing the vagina and its secretions, which they then taste. If the male

chooses to mate with the female, she is likely to give a copulation call during coitus, which may indicate further aspects of her status to this and other males”.

Fixed multimodal signals are those whose components are obligatorily coupled due to the mechanics of signal production (e.g., a “scream face” necessarily accompanies a “scream” vocalization in chimpanzees) (Smith 1977). By contrast, free multimodal signal combinations are those whose component signals may be produced separately or combined flexibly with other signals (Tomasello 2008). From the perspective of perception, cross-modal integration of vocal and visual signal elements has been shown in both monkeys and great apes, which were able to recognize the correspondence between species-specific facial and vocal expressions, termed “audio-visual matching” or “face/voice integration” (Partan and Marler 2005). From the production side, several studies in both wild and captive environments indicated that great apes use signal combinations conveying context-specific information that would not be available from a single sensory input (Liebal et al. 2013). For instance, male bonobos have been shown to use the same vocalization (“contest-hoot”) for play and aggression, but add gestures to distinguish between the two contexts (Genty et al. 2014). This way ambiguous messages sent in one channel can be clarified by adding a more specific component in another channel (Partan and Marler 2005).

### Conclusion

Catarrhine primates, like most other animals, produce and perceive signals of various sensory modalities. The modalities employed are thought to underlie the heavy influence of social and ecological factors. Primates are generally thought of as “visual” mammals, as they exhibit an elaborated visual system with forward-directed large eyes enabling stereoscopic vision. Accordingly, the largest variety of signals is found in this domain, including colorful sexual swellings, facial expressions, and gestures. Sound also plays a major role in catarrhine life, with

vocalizations used to defend territories and food resources, negotiate social interactions, and to locate conspecifics. Touch is an often-neglected sense of communication in primates, but signals involving body contact have been shown to play an essential role in affiliation and mother-infant coordination. Although primates are traditionally considered microsmatic, olfactory signals (i.e., pheromones) are used by catarrhines in the recognition of the reproductive status of females. Catarrhines frequently combine signals from different sensory modalities simultaneously and sequentially, thus research on single modalities in isolation results in missing much of the complexity inherent to communicative acts. Moreover, future studies of primate communication should adopt a multimodal, inclusive approach focusing on modalities in terms of both production and perception (Liebal et al. 2013; Fröhlich 2017). If primate communication is examined from the perspective of the signaler and signal form alone, researchers might fail to distinguish the proximate from the ultimate explanations for signals.

long periods of gestation and nursing and have high encephalization quotients (brain to body ratio), thus requiring large amounts of energy to function properly. The energetic demands of primates' large brains alone require daily consumption of large amounts of energy-rich foods (Aiello and Wheeler 1995).

Within the diverse parvorder *Catarrhini* (which encompasses old-world monkeys, apes, and humans), there is a great deal of dietary variability, ranging in degree of folivory (leaf eating), frugivory (fruit eating), granivory (seed eating), and graminivory (grass eating). Lambert and Rothman (2015) state that most primate species are in fact what they call “flexible omnivores,” meaning that not only do primate species switch between different food sources, but that the foods themselves (both food type and nutrient composition) vary based on location, seasonality, and time of day. Even among many of the catarrhine species who are classified under the dietary categories of “folivore” or “frugivore,” there is still a great deal of dietary variability. It should be noted that even with this dietary flexibility, there are still a few primates that will preferentially select, and are specialized for, certain types of foods (i.e., leaf-eating colobines, grass-eating gelada baboons, etc.). Additionally, within all primate species, the use of fallback foods, or foods that are eaten when preferred foods are unavailable, is regularly observed. Moreover, large-bodied primates, such as catarrhine species, serve a vital role as seed dispersers which aid in the development and maintenance of the ecosystems and habitats (primarily forested areas) in which they live.

## Catarrhine Diet

B. Katherine Smith  
The University of Southern Mississippi,  
Hattiesburg, MS, USA

## Introduction

Most primates are morphologically and physiologically adapted as frugivores and seek out energy and nutrient-dense foods. Primates have

## Old-World Monkeys

The largest group, with the most species within *Catarrhini*, is the old-world monkeys. Old-world monkeys range throughout the continents of Asia and Africa (and one species in South Europe), are typically larger bodied than their New World counterparts, and are generally flexible feeders. Within the old-world monkeys are the two subfamilies Colobinae (African and Asian colobines) and Cercopithecinae (cheek-pouched monkeys).

## Colobines

Colobines are also known as the “leaf-eating” monkeys, though their diet is much more complex and varied (Fashing 2011; Kirkpatrick 2011). All colobines have specialized multi-chambered or sacculated stomachs that allow for fermentation of high-fiber foods (Kay and Davies 1994). This fermentation process also helps to detoxify plants and is achieved by the symbiotic relationship with species-specific microbiota that live in their intestines. This ability to ferment low-quality foods, such as mature leaves, allows for colobines to survive on a diet many other animals could not. Moreover, all colobine species have adaptations in addition to sacculated stomachs that allow them to process leaves including enlarged salivary glands and molars capable of processing tough plant foods. Colobines tend to prefer young leaves and fruit to mature leaves but will forage and feed on mature leaves when necessary.

*Asian colobines:* Asian colobines have, according to Kirkpatrick (2011), diets that vary by season and include leaves, fruits, and seeds. While most Asian colobines’ diet is primarily leaves, Kirkpatrick (2011) states that about a quarter of their diet consists of fruits and seeds, and while invertebrate consumption is rare, it does occur (Newton 1992).

*African colobines:* Like their Asian counterparts, African colobines are leaf-eating monkeys. However, similar to the Asian colobines, their diet does alter seasonally, and fruit, seed, and flower consumption is regularly observed. While some of the larger-bodied African colobines don’t have a problem relying on mature leaves when other food sources aren’t available, some of the smaller-bodied species might not be able to ingest such low-quality foods.

## Cercopithecines

The cercopithecines span both the continents of Asia and Africa (and one macaque species in Gibraltar). These primates, which share morphological characteristics of cheek pouches and ischial callosities (thick-callused pads on the buttocks), include African papionins (baboons, gelada baboons, mangabeys, mandrills, drills),

macaques (the most successful primate species, second only to humans), guenons, and vervets. Save the gelada baboon, cercopithecines are largely flexible omnivores, though like all other primates, foods are chosen based on nutrient content.

***Baboons and Baboon-Like Primates*** Baboons (*Papio* sp.) eat a wide variety of foods and are considered opportunistic omnivores. As they are the most widely disbursed primate in Africa, troop diets may vary depending on location. For example, baboons who live near the ocean have been observed eating and foraging for shellfish and mermaid’s purses (shark eggs), while some baboons who live near soda lakes hunt for flamingo. Many of these foraging strategies are culturally passed from generation to generation. Additionally, they use their short, dexterous fingers to dig for underground storage organs and feed on flowers, fruits, gums, seeds, leaves, grasses, and various animal prey. Baboons tend to choose diets that are low in fiber, high in protein, and high in fat. As baboons are capable of a great deal of dietary flexibility and as human and baboon populations continue to collide, baboons have begun foraging in trash heaps, crops, and settlements.

One interesting and specialized cercopithecine that is commonly referred to as a baboon, though not a member of the genus *Papio*, is the gelada baboon (*Theropithecus gelada*). Gelada baboons are grass specialists (graminivores) who spend their days foraging on the grasses in the highlands of Ethiopia, the only place in the world where they are found. Because they spend their days foraging on grasses and sitting down, some interesting behavioral and morphological adaptations have emerged. Behaviorally, gelada “chatter” or verbally groom one another throughout the day, as they don’t have the time to physically groom one another. Morphologically, gelada have bald, red patches on their chests which indicate health and reproductive status.

***Macaques*** Macaques are the most widely disbursed and successful primate, other than humans, in the world. They range throughout Asia and are

also found in North Africa and in Gibraltar. Macaques successfully live and thrive in varied habitats and climates ranging from Southern India to mountainous regions in Japan, with heavy snowfall. Macaques are generally thought of as frugivores; however, depending upon seasonality and habitat, their diet can include a great deal of other foods including seeds, animal protein (invertebrates), bark, leaves, flowers, herbaceous growth, and roots. Many macaques are also heavily reliant on humans as a food source either through crop raiding or at temples or tourist spots, where they are provisioned.

## Apes

Apes show varying reliance on fruits, but all are considered somewhere on the spectrum of a frugivore-folivore or folivore-frugivore. Apes are the largest bodied and have the highest encephalization quotient (brain to body ratio) of all of the primates. While some apes (i.e., mountain gorillas) are more folivorous than frugivorous, the majority shows a preference for fruits, which are higher quality and have higher calorie content, supporting the energetic demands of a larger brain and body. Among the great apes, which includes chimpanzees (*Pan troglodytes* sp.), bonobos (*Pan paniscus*), orangutans (*Pongo abelii* and *Pongo pygmaeus*), gorillas (*Gorilla gorilla* sp. and *Gorilla beringei* sp.), and ancient and modern humans and their ancestors (*Australopithecus* sp. and *Homo* sp.), diets include, but are certainly not limited to, fruits, leaves, piths, and invertebrates. It has been shown that when given the opportunity, all great apes will preferentially eat fruits (Remis 2003).

### Asian Apes

**Gibbons and Siamangs** Gibbons and siamangs are the smallest bodied of the apes, which allow them to utilize more of the forest canopy than some of their conspecifics and are found only in Southeast Asia. Gibbons are highly frugivorous, relying most heavily on ripe fruits, though some

species are more folivorous than others. Diet also consists of flowers, insects, and young leaves.

**Orangutans** Orangutans are a highly frugivorous species which impacts their overall social structure. Some of the preferred foods of orangutans are durian fruit and figs. Additionally, tool usage has been observed in orangutans to obtain insects and saps from trees as well as hunting of other animals (i.e., slow loris) (van Schaik et al. 2003). As they are the largest-bodied arboreal animal, and trees fruit in patches, it's difficult for orangutans to live in social grouping. Females and their offspring will live together for up to 8 years, while dominant, or flanged, males will overlap in range with multiple females and their offspring.

Every few years, an ecological phenomena known as a masting or mast fruiting will occur, which produces an abundance of fruits on multiple trees of the same species simultaneously, allowing for large numbers of orangutans to congregate. Orangutans in the wild have been known to become obese during a mast fruiting. When mast fruiting occurs, orangutans will switch from their typical diet of leaves, bark, and some fruits to gorge themselves solely on high calorie fruits and fatty seeds until they are no longer available. It is not uncommon for orangutans, at the end of these periods of fruit abundance, to have enlarged fat deposits, which they rely on during the fruit scarcity that follows a mast fruiting.

### African Apes

**Gorillas** Habitat, elevation, and ecological niche greatly influences the diet of gorillas, the largest-bodied living (or extant) primate. Much of our knowledge of gorilla diet, ecology, and behavior come from the groundbreaking work on mountain gorillas (Fossey and Harcourt 1977; Schaller 1963). Because of these studies, all gorillas were long thought to be ground-dwelling leaf eaters. However, while mountain gorillas are specialized to higher altitudes and do forage mainly on the ground for leaves and herbaceous growth (Fossey and Harcourt 1977; Schaller 1963), western lowland gorillas are typically found in lower-altitude

forests with a diet that varies seasonally (Yamagiwa and Basabose 2006). Moreover, western lowland gorillas are known to spend time in the trees, with females being able to move among the higher and smaller branches as they are smaller bodied and more agile than males. This increased access to multiple levels of the forest allows for more food availability for females and juveniles.

Western lowland gorillas are now commonly classified as folivore-frugivores, as they prefer ripe fruit but will utilize leaves and herbs as staple foods and fallback foods (Remis 1997, 2003; Yamagiwa and Basabose 2006). Additionally, they will eat invertebrate animal prey (Tutin and Fernandez 1985) (typically by breaking open termite mounds), though it is not a significant source of their daily protein intake. High fruit consumption occurs during seasons when fruit availability is higher (Goldsmith 1999; Remis 1997), but they will switch to lower energy, fibrous herbs, leaves, and bark, when fruit availability is scarce (Dierenfeld 1997; Goldsmith 1999; Masi et al. 2009; Remis 1997; Rothman et al. 2008; Wobber et al. 2008).

Gorillas have an enlarged cecum and colon (portions of the large intestine) that is rich in species-specific gut microbiota, which facilitate the digestion of a high-fiber diet (up to 200 g/day). Wild gorilla diets are high in many vitamins and minerals, though sodium is often sought out in various ways depending on the species. Where mountain gorillas will eat decaying wood as a source of sodium, western lowland gorillas will travel to clearings in the forest called salines (along with other species, including forest elephants), to ingest mineral-rich soils.

**Chimpanzees and Bonobos** Chimpanzees in the wild eat a variety of foods including fruits, leaves, herbs, bark, and invertebrate and vertebrate animal protein (including eggs) (Wrangham 1977; Goodall 1986). Both chimpanzees and bonobos are highly frugivorous, and most of the protein content of their diets are plant based in the form of herbaceous leaves. In addition, chimpanzees are successful hunters and often cooperate together to

obtain prey. A favorite food of chimpanzees, where available, are red colobus monkeys. Bonobos, on the other hand, rarely eat animal protein (though they will eat duiker sporadically) and eat a more frugivorous-folivorous diet. Chimpanzees and bonobos both regularly utilize tools to extract foods, most famously for termite fishing.

**Hominins: Humans and Their Ancestors** The similarities between the diets and dietary preferences among extant African apes and modern humans, prior to domestication, suggest that our last common ancestor likely shared a similar diet. For instance, gorillas, chimpanzees, and humans share similar gut morphology (Chivers and Hladik 1980), save the elongated large intestine of the gorilla. Moreover, apes and humans exhibit taste perception and food preferences that overlap (Dierenfeld 1997; Masi et al. 2009; Remis 1997; Rothman et al. 2008; Wobber et al. 2008). These similarities suggest that diets of very early hominins were likely more similar to those of extant (living) African apes than to contemporary human populations.

As hominins diverged from the common ancestor shared with gorillas and chimpanzees, there were shifts in diet, including the emergence of food preparation (Conklin-Brittain et al. 2002; Marshall and Wrangham 2007; Wobber et al. 2008; Wrangham 2009), food acquisition (and thus a greater variety in foods eaten), and eventually domestication. Changes in diet and the coinciding physical adaptations, including changes in cranial and dental morphology, are considered hallmarks in hominin evolution. As soft tissue cannot fossilize, it has been hard to understand the full morphological consequences of these dietary shifts to early hominin digestive anatomy and physiology over the course of evolution. However, while generalized gut morphology can be reconstructed from changes in torso shape in fossil species (Aiello and Wheeler 1995), gut morphology is plastic and is able to change in minor ways over short periods of time, depending on diet (Milton 1999).

The use of fire and subsequent heating and cooking of hominin foods alter the chemical structure and nutritional composition of consumed foods

(Wrangham 2009). Moreover, a study has shown that even captive great apes, who have never eaten cooked food, when given the option, prefer it (Wobber et al. 2008). In addition, as hominins moved out of the forest and into the savanna, fallback foods likely shifted to underground storage organs (i.e., roots and tubers), which are lower in fiber content and more calorically dense than typical forest fallback foods such as mature leaves, herbaceous leaves, bark, and pith (Conklin-Brittain et al. 2002). Moreover, fossil evidence suggests that during this time, hominins increasingly relied on wild game (Milton 1999).

While the advent of agriculture and crop domestication is relatively recent from an evolutionary perspective, humans have been domesticating and eating grains and other soft foods for thousands of years. Even with this prolonged exposure, humans physically appear to have been unable to keep pace with the myriad of dietary changes that have occurred with the advent of agriculture and the Industrial Revolution (Milton 1999).

### Synonyms

Apes; Old world monkeys; Lifestyle;  
Reproduction

### Definition

A general life history of the primate parvorder Catarrhini (Old World monkeys, gibbons, and great apes).

### Introduction

Catarrhine primates include species from three families: Cercopithecidae (Old World monkeys; 159 extant species), Hylobatidae (gibbons and siamangs; 19 extant species), and Hominidae (great apes and humans; 7 extant species; Mittermeier et al. 2013). Most nonhuman

Catarrhini are found in tropical and subtropical forest habitats throughout parts of Europe, Asia, and Africa (Redmond 2008). Many species within this parvorder are listed by the International Union for Conservation of Nature (IUCN) as vulnerable, endangered, or critically endangered, primarily due to hunting and habitat loss from logging, urbanization, and human agricultural activity (Mittermeier et al. 2013). Catarrhine primates are generally long-lived and highly social, with complex social organization. This paper addresses key life history traits for this parvorder, focusing primarily on reproduction, growth, lifespan, and social structure. Information on diet, communication, and cognition within the parvorder Catarrhini is covered elsewhere within this encyclopedia and will not be addressed here. Human (*Homo sapiens*) life history parameters will not be included in this entry.

### Life History Parameters

Key life history parameters discussed below are reviewed for all extant catarrhine species in Mittermeier et al. (2013).

### Reproductive Cycles

The ovulation cycle of catarrhine primates ranges from 22 to 52 days, though 30–35 is typical. Unlike other mammalian species, catarrhine reproductive cycles include a period of menstruation, generally lasting 1–8 days (Hrdy and Whitten 1987). Female signaling of sexual receptivity often involves both physical and behavioral cues. In many catarrhine species, females exhibit only moderate swelling or color change of the skin surrounding the genitals; however, in some species, the physical changes are much more conspicuous and include large perineal swellings and/or reddening of the face or perineum (Hrdy and Whitten 1987). In Gelada baboons, cutaneous vesicles (blisters) also swell on the bare skin of the chest/ventral area and change color over the course of the reproductive cycle (Alvarez 1973). Olfactory cues, such as vaginal secretions, are also used in many primates as an indicator of a female's reproductive state (Hrdy and Whitten

1987). Behavioral signals of female sexual receptivity include a variety of solicitation postures and gestures, such as the presentation of hind-quarters, head-shaking, and crouching (Hrdy and Whitten 1987).

### Reproductive Maturity

Across parvorder Catarrhini, it is typical for females to become reproductively mature well before males. However, it should be noted that it is often difficult to determine when males become reproductively mature in a number of species as males often do not show obvious signs of maturity and may not reach their full reproductive potential until they are able to physically compete for females, which may be several years after the testes begin to produce viable sperm (Alberts and Altmann 1995). Age of sexual maturity seems to be related to adult brain size (Harvey and Clutton-Brock 1985), with larger bodied individuals (e.g., great apes) experiencing a longer period of development. Environmental factors (e.g., access to food resources) and social factors (e.g., stress, harassment) also play a role in age of sexual maturity. For instance, in some species, such as rhesus macaques, higher-ranking females become sexually mature before lower-ranking females as these individuals have more access to food and experience lower levels of social stress due to their rank (Melnick and Pearl 1987).

### Reproductive Seasonality

Reproductive seasonality is variable among catarrhine primates, though it tends to be more common in species that live in temperate regions or high elevations (Zinner et al. 2013). Seasonality is predominantly driven by the availability of primary food sources, though whether this food availability is timed for copulation (to initiate breeding cycle) or birth (ensuring sufficient energy for lactation) depends on the predictability of the environment (Brockman and van Shaik 2005). Harsh environmental conditions can also contribute to reproductive seasonality. For instance, in black-and-white snub-nosed monkeys (*Rhinopithecus bieti*) living in the eastern Himalayan highlands where winter temperatures

are often below freezing, birthing is timed to take place when temperatures are increasing (Huang et al. 2012).

### Gestation, Birth, and Weaning

Gestation periods within Catarrhini range from 4 months to 9 months, with longer gestation periods being associated with larger adult body size (Harvey and Clutton-Brock 1985). Females typically give birth to a single offspring per birth; twin births can occur but are rare (Williamson et al. 2013; Zinner et al. 2013). Weaning in Old World monkeys typically occurs between 1 and 2 years of age (Zinner et al. 2013), while in the great apes, offspring are not weaned until 3–8 years (Williamson et al. 2013). Females typically do not give birth to another offspring until their current offspring is weaned, thus, in species in which infanticide is common (e.g., baboons, some colobus), females may wean their infants early in order to reduce interbirth intervals (Zinner et al. 2013).

### Dispersal

In most catarrhine species, dispersal is male-biased, with males typically leaving their natal groups upon reaching sexual maturity (Pusey and Packer 1987). Female dispersal is not common but occurs among the great apes and a few species of Old World monkey, whereas both sexes disperse in several species of langur and red colobus (Williamson et al. 2013; Zinner et al. 2013). If males do not immediately transfer to a new group upon leaving their natal group, they may live as solitary individuals or form an all-male group with other males. Species living in open habitats (e.g., Gelada baboons, *Theropithecus gelada*, and patas monkeys, *Erythrocebus patas*) are more likely to create all-male groups, likely to reduce predation risk (Pusey and Packer 1987).

### Body Size

Body size among catarrhine primates is highly variable. The smallest species (Southern talapoin monkey, *Miopithecus talapoin*) weighs in at approximately 1 kg, while the largest (Eastern gorilla, *Gorilla berengei*) can weigh up to

209 kg (Mittermeier et al. 2013). There is sexual dimorphism among most catarrhines, with female weights typically being 50% that of males; however, extreme sexual dimorphism is prevalent only among a few species of Old World monkey (mandrills/drills, *Mandrillus* spp.; baboons, *Papio* spp. and *Theropithecus gelada*) and the great apes. Arboreal species tend to be smaller than terrestrial species as large body size is a disadvantage when moving through dense vegetation and accessing fruits or young leaves located on thin terminal twigs (Harvey and Clutton-Brock 1985).

### Lifespan

Little information is known about the longevity of catarrhine primates as the sustained observations of many decades that would be required to determine lifespans are generally not feasible in most areas. Therefore, much of what is known about lifespan in primates comes from data collected from captive primates (Hakeem et al. 1996), though long-term studies have been carried out for some species (Williamson et al. 2013). Lifespan in Old World monkeys ranges from 18–45 years, while gibbons and great apes generally have longer lifespans (30–58 years). There appears to be a moderate correlation between lifespan and adult brain size (Harvey and Clutton-Brock 1985).

### Social Organization

For species-specific social organization parameters, see Mittermeier et al. (2013).

### Group Composition

Catarrhine primates are highly social, spending much of their time traveling, interacting, and foraging in groups. Group composition is highly intertwined with mating strategy, though foraging strategy, habitat size, and predation pressure also contribute to group living dynamics. The most common grouping patterns in catarrhine primates include multiple male, multiple female groups and single-male, multiple female groups; however, the number of females in these groups is highly variable, even within a single genus

(Wrangham 1987). For instance, the Angolan colobus (*Colobus angolensis*) lives in small groups of 3–4 individuals with a single male, while the Gureza (*Colobus guereza*) is commonly found in groups of 6–10 with a single male (Zinner et al. 2013). Generally, groups are more likely to consist of multiple males when there is a large number of females in the group (Mitani et al. 1996) or if there is overlap in female breeding receptivity (Nunn 1999). Increased predation risk might also lead to a greater number of males within a group, as is the case for several species of *Colobus* in Africa in which adult monkeys are susceptible to predation by eagles (Van Shaik and Höstermann 1994). Monogamous pair-living, which consists of monogamous parents and two or three offspring (Redmond 2008) is comparatively rare among catarrhines and seems to be primarily limited to the Family Hylobatidae (Wrangham 1987). Only one catarrhine, the orangutan (*Pongo* spp.), is considered semi-solitary, which is due to a greater spacing between individuals than is observed in other primate species. However, the social organization of this species might better be described as loose communities, centered around a single, dominant long-calling male (Delgado and van Shaik 2000).

### Group Size

Group size within Catarrhini is highly variable, ranging from small family groups of 2–6 individuals to extremely large groups consisting of several hundred individuals. Group size is driven by both ecological (e.g., predation pressure, food distribution, and habitat structure) and social factors (e.g., mating strategy, intergroup interactions, and infanticide; Wrangham 1987). In some catarrhine species (e.g., *Macaca fascicularis*, *M. fuscata*, *M. sinica*, *Pan troglodytes*), individuals generally live in large groups, but divide regularly into smaller groups during foraging. It is more common among Catarrhini for small groups to fuse with others to form “supergroups.” A notable example of this is found in hamadryas (*Papio hamadryas*) and gelada baboons (*Theropithecus gelada*), where the basic social unit is a single male with multiple females and their dependent offspring. However, these social units join

together with several others to form “clans” and several clans often join together to form “bands” of up to 1000 individuals (Zinner et al. 2013). Similar multi-level societies are found in snub-nosed monkeys (*Rhinopithecus* spp.), doucs (*Pygathrix* spp.), and proboscis monkeys (*Nasalis larvatus*; Zinner et al. 2013).

### Parenting

Compared to other mammals, primate infants are born altricial and undergo a lengthy period of dependency on their parents (Nicolson 1987). During this time of dependency, young primates learn how to forage, recognize and escape predators, and the social rules of the group (Preston-Mafham and Preston-Mafham 1999). Parental investment may differ between male and female infants in some species, with male infants requiring more parental care than females (Arlet et al. 2014). The care of young primarily falls to the mother, though there are some exceptions, the most notable of which is the Siamang (*Sympalangus syndactylus*). Male siamangs take over as the primary caregiver in the second year of life, which may serve to reduce the period of infertility following cessation of lactation in females, leading to a shorter interbirth interval (Lappan 2008). Infants are carried on the bodies of their parents, either ventrally or dorsally. Female olive colobus (*Procolobus verus*) are known to carry infants in their mouth for the first few weeks of life, likely due to short hair that is difficult for the infant to cling to (Zinner et al. 2013). Alloparenting, in which individuals other than the parents care for the offspring, is observed in a number of catarrhine species but is particularly common among Asian colobines. Typically, alloparents are related females, though in some species males may engage in alloparenting behavior (e.g., Barbary macaque, *Macaca sylvanus*; Olive baboons, *Papio anubis*; mountain gorillas, *Gorilla beringei*; Whitten 1987). Alloparenting may serve a variety of functions, including: mothering practice, enhanced status of alloparent, increased foraging efficiency of mother, increased survival of orphaned infants, and infant protection from conspecifics (Nicolson 1987; Whitten 1987).

### Grooming

Social grooming (also called allogrooming) consists of the manipulation of skin and hair of another individual (Cooper and Bernstein 2000) and is observed across a number of catarrhine species. Such behavior can take on many forms and involve a variety of individuals. For example, bonobos engage in grooming cliques, in which one individual receives grooming from three others, while in grooming clusters a larger number of individuals (range: 2–11 individuals) groom one another (Sakamaki 2013). Mutual grooming in bonobos occurs between one adult male and one adult female, whereas triadic grooming clusters involve two adults and one juvenile or infant (Sakamaki 2013). In gorilla troops, the dominant male may groom adult females, but he will also allow young juveniles to groom him (Preston-Mafham and Preston-Mafham 1999). While allogrooming may serve the purpose of removing ectoparasites and dirt from areas individuals cannot reach themselves (Hutchins and Barash 1976), the behavior primarily serves a social function. Allogrooming is generally used to build and maintain relationships between group members (Dunbar 1991), but it may also be used to obtain access to or maintain proximity with sexual partners (D’Amato et al. 1982; Gumert 2007), to obtain aid or defense in future agonistic encounters (Seyfarth and Cheney 1984), or as a mechanism for reducing tension or reconciling after agonistic encounters (Shino et al. 1988).

### Conclusion

Parvorder Catarrhini includes Old World monkeys, gibbons, and great apes. While all catarrhines are long-lived and highly social, the diversity of species within this parvorder makes it difficult to make generalizations about their life history patterns or behavior, even within the same family or genus. Variability in ecological and social conditions contribute greatly to this diversity. Members of the family Homonidae are the most different among the catarrhines, with longer gestation and weaning periods, later reproductive maturity, and longer lifespans.

Campus- Philadelphia College of Osteopathic  
Medicine, Suwanee, GA, USA

Synonyms

Cercopithecine; Cercopithecoid; Colobine;  
Hominoid

Definitions

- Bipedal      Locomoting using only hind limbs for support and propulsion.
- Brachiation      Below branch, hand-over-hand suspensory locomotion, where body weight is supported by the forelimbs. This is also sometimes known as “arm-swinging.”

- Bridging      Crossing a gap in the canopy where contact with one support is maintained while contact is made with another.
- Climbing      Progression up a vertical or near-vertical support
- Digitigrade      A locomotor posture where the mass of the forelimb is supported by the digits and metacarpal heads of the hand. The palm does not contract the substrate.
- Knuckle-walking      A form of quadrupedal locomotion where the mass of the forelimb is supported by the second to fifth middle phalanges of the hand.
- Leaping      Propulsion, primarily by the hind limbs, as a means of crossing gaps in the canopy.
- Palmigrade      A locomotor posture where the palm and fingers of the hand contact the substrate, which is either ground or branch.
- Quadrupedal      Locomoting using all four limbs for support and propulsion. Above-branch quadrupedalism is progressing by walking or running on top of tree branches, with terrestrial quadrupedalism on the ground.
- Scrambling      An above or below branch progression in which each limb grasps a different support.

Introduction

Catarrhines are a monophyletic group of primates divided into two taxonomic superfamilies: Cercopithecoidea and Hominoidea. Cercopithecoids are Old World monkeys (those found in Africa and Asia), and hominoids are apes, including humans. Cercopithecoids currently have greater species numbers, wider geographic distribution, and more diverse ecological niches, whereas modern apes are less species rich but are more diverse in terms of postcranial morphology and locomotor behavior. This can largely be explained by comparing the evolutionary

history of each group. Hominoids were more diverse both taxonomically and behaviorally and also had a wider geographic range during the Miocene (23–5 million years ago) (Ward 2015). Since then, apes have become geographically more restricted such that modern apes are now limited to the tropical forests of Africa and Asia. The cercopithecoid radiation, by contrast, is much more recent. Modern Old World monkeys are currently species rich but have diverged less in locomotor behavior (Fleagle 2013).

Locomotor behavior is strongly tied to postcranial morphology, especially the proportions and features of the limbs. Differences in locomotor behavior are reflected in the postcranial morphology among hominoids and cercopithecoids. Overall, catarrhines have a relatively primitive mammalian body plan, as do primates in general. Unlike other mammals, primates lack specializations like hooves or wings but retain four limbs with grasping digits and opposable thumbs and big toes (with some exceptions). Catarrhines differ from one another mainly in terms of degrees, such as lengths of the limbs, digits, or tail. One common measure of these differences is the intermembral index (IMI), which gives the relative lengths of the forelimb to the hind limb. It is measured as a ratio of humerus plus radius length over femur plus tibia length (usually multiplied by 100 for ease of interpretation). Therefore, any animal with an IMI of 100 has equally long forelimbs and hind limbs. A value of less than 100 indicates longer hind limbs than forelimbs, whereas a value greater than 100 indicates longer forelimbs. Intermembral indices reported here are from Napier and Napier (1967).

## Cercopithecoids

Cercopithecoids are divided into two subfamilies, cercopithecines (including baboons, macaques, and guenons) and colobines (including leaf-monkeys, langurs, and African colobus). A typical cercopithecoid monkey is an arboreal quadruped, walking above branches on all four limbs in a palmigrade posture. Many cercopithecines spend much of their time on the ground, whereas most

colobines are entirely arboreal. Traveling between trees is often done by leaping, although colobines generally leap with greater frequency and over farther distances than cercopithecines. Forelimb suspension (progressing below branches using only the forelimbs) has been recently reported among certain larger-bodied colobines but is not seen among cercopithecines.

The Old World monkey body plan reflects adaptations for running and leaping, either on the ground or in the trees. They have a long, flexible back with seven lumbar vertebrae, a mediolaterally narrow but dorsoventrally deep thorax with laterally placed scapulae, and retain a tail. Like all primates, they have grasping digits, with opposable thumbs and big toes (with the exception of *Colobus*, see below). Grasping hands and feet are crucial for arboreal travel. The shape of the thorax places the feet near the midline for efficient running, the flexible back provides a greater range of flexion and extension for propulsion during running and/or leaping, and the tail acts as a balancing organ.

## Cercopithecines

Cercopithecines are largely found in Africa and are quadrupeds that mainly differ in the extent to which they are terrestrial. While cercopithecines range from almost entirely terrestrial to almost entirely arboreal, most are primarily arboreal with some terrestrial behavior. Nonetheless, the variation in degree of terrestriality has relatively little effect on the overall cercopithecine body plan. More terrestrial forms tend to have more equal limb lengths and shorter digits and walk in a digitigrade posture, whereas arboreal forms have longer hind limbs, a longer tail, and longer digits and walk in a palmigrade posture. Since even the more terrestrial forms still forage and/or sleep in trees, these similarities are likely related to the necessity of safely utilizing the arboreal environment (Rollinson and Martin 1981).

Macaques (genus *Macaca*) are the most geographically widespread nonhuman primates, ranging from Morocco to Japan to Bali, in a broad range of environments. Macaques differ in size and tail length between species, but overall, their relatively generalized body plan allows them to exploit

environments as different as the deserts of Morocco to the temperate, snowy forests of Japan. Macaques are quadrupeds that engage in infrequent leaping. Their behavioral adaptability allows more than one macaque species to live in the same geographic range. For example, in Borneo, the larger pig-tailed macaque (*M. nemestrina*) is largely terrestrial (but still feeds in trees), whereas the smaller, sympatric long-tailed macaque (*M. fascicularis*) is almost entirely arboreal (Rodman 1991).

Mangabeys (*Cercocebus*, *Lophocebus*, *Rungwecebus*) are forest dwellers in Africa. Species of the genus *Lophocebus* are arboreal quadrupeds, whereas *Cercocebus* is largely terrestrial (Gebo and Chapman 1995; McGraw 1998a). While these taxa have largely similar body plans, *Cercocebus* limb bones show features related to terrestriality not seen in *Lophocebus* (Nakatsukasa 1996). The kipunji (*Rungwecebus*) has only been described recently, and their locomotor behavior is currently not well known.

Baboons are the largest monkeys. Savannah baboons (*Papio*) are found in Africa and the Arabian Peninsula in a wide variety of habitats, from semidesert and savannah to woodland and tropical forest environments. They are the most terrestrial monkeys, which are reflected in their postcranial morphology. Baboons have fore- and hind limbs of roughly equal length (IMI of 95); a long, narrow scapula; and short digits on their hands, which they utilize in a digitigrade posture when walking. Despite these terrestrial adaptations, baboons sleep either in trees or on rocky outcroppings, and as such, they still retain grasping thumbs and big toes to engage in arboreal locomotion.

The gelada baboon (*Theropithecus*) is found in the highlands of Ethiopia. They live in grasslands but sleep in rock formations at night. Like savannah baboons, they have limbs roughly equal in length (IMI of 94), with short digits and are digitigrade.

Mandrill (*Mandrillus*) behavior has not been extensively studied, but mandrills live in dense tropical forests of Africa, where they are known to forage along the forest floor (Swedell 2011). Morphologically, mandrills are similar to baboons in that they are large-bodied, have relatively equal limb lengths (IMI of 94), and have short digits with large thumbs.

Guenons (*Cercopithecus*), and their close relatives, the swamp monkeys (*Allenopithecus*) and the Talapoin monkey (*Miopithecus*), are found primarily in the tropical forests of Africa. They are quadrupedal, primarily arboreal, leap less frequently than colobines (see below), and vary between species as to the amount of terrestrial and arboreal locomotion. For example, the blue monkey (*C. mitis*), Diana monkey (*C. diana*), and Talapoin monkey (*Miopithecus*) are almost entirely arboreal. De Brazza's monkey (*C. neglectus*), L'Hoest's monkey (*C. lhoesti*), and Campbell's monkey (*C. campbelli*) are partly terrestrial, while the sun-tailed monkey (*C. solatus*) is largely terrestrial (McGraw 2002). Guenon species are often sympatric, but will occupy different levels of the canopy. Despite the differences in the amount of terrestriality, guenons are largely similar in terms of postcranial anatomy, such as possessing relatively long hind limbs (IMI of around 80), typical of most cercopithecines.

Vervet monkeys (*Chlorocebus*) are closely related to guenons and are found in African woodland habitats. They are described as "semiterrestrial," although one study found only 20% of activity was terrestrial (which is less than some of the guenons above) (Rose 1979). Perhaps due to this close relationship and retained reliance on arboreal settings, vervets have similar limb proportions to guenons (IMI of ~80).

Patas monkeys (*Erythrocebus*) live in wooded steppe and woodland habitats. They are largely terrestrial quadrupeds and are the fastest primates, having been clocked running 55 km/h (~34 mph) (Hall 1966). They have long limbs that are roughly to equal in length (IMI of 92), which provide them with a long stride. They have short fingers and are digitigrade when walking on the ground. Like other monkeys, they climb into trees to feed or rest. Because most trees in their habitat are widely spaced, they usually walk between trees but will leap across narrower gaps.

### Colobines

Colobines are found in both Africa and Asia, with separate radiations on each continent. Compared to cercopithecines, colobines are more arboreal and leap both farther and with greater frequency

(Gebo and Chapman 1995). Colobines, like other leapers, tend to have longer hind limbs compared to forelimbs. Colobines also tend to have long digits but reduced thumbs. There are a few exceptions among the larger-bodied Asian colobines, with some semiterrestrial forms and some that display suspensory locomotor behaviors.

The three genera of African colobus monkeys are named by their coat color: black and white colobus (*Colobus*), olive colobus (*Procolobus*), and red colobus (*Piliocolobus*). All are forest-dwelling leapers and arboreal quadrupeds. In one study, all three African colobine genera were found to leap with more frequency than two guenon and a mangabey species living in the same forest (McGraw 1998a). The black and white colobus and olive colobus are typical of colobines, in that they have relatively long hind limbs (IMI of ~80) and long tails. They have short thumbs, and one species of black and white colobus in particular, *Colobus guereza*, lacks an external thumb altogether.

The red colobus, like other African colobines, is an arboreal quadruped and leaper. However, they will also commonly engage in climbing and scrambling behaviors (McGraw 1998b). The red colobus will occasionally hang by their forelimbs. Other African colobines will land from leaps on top of branches on all four limbs, while the red colobus will swing below the branch by its forelimbs. The red colobus has longer forelimbs than the black and white colobus.

Asian colobines are divided into two groups, the langurs or leaf monkeys and the odd-nosed monkeys. The langurs are largely typical colobine arboreal quadrupeds and leapers, with the exception of the Hanuman langur, which is partially terrestrial. Odd-nosed monkeys are larger in body size and more diverse in their locomotor behaviors.

Langurs of the genera *Presbytis* and *Trachypithecus* are found in South and Southeast Asia. Both taxa are arboreal quadrupeds and engage in leaping. All have longer hind limbs than forelimbs, typical of leapers (IMI of ~80). A comparison of *Trachypithecus obscurus* and *Presbytis melalophos* in Malaysia found that both were quadrupedal and leapers, with

*T. obscurus* primarily quadrupedal and *P. melalophos* relying more on leaping and also engaged in occasional arm-swinging (Fleagle 1978). Delacour's langur (*T. delacouri*) is quadrupedal but spends much of its time on cliff faces in Northern Vietnam (Workman and Schmitt 2012).

The gray or Hanuman langur (*Semnopithecus*) has a range from Sri Lanka to the Himalayas. They are roughly equally terrestrial and arboreal. They are perhaps the most terrestrial colobine and among the most adaptable (Ripley 1967). They have long limbs but with limb proportions similar to arboreal, leaping leaf monkeys.

Odd-nosed monkeys are among the least studied, but what is known shows that they are the most variable colobines in their locomotor behavior. The snub-nosed monkey (*Rhinopithecus*) ranges from tropical Vietnam to temperate China, where snow is typical in winter. *Rhinopithecus roxellana* and *R. bieti* are partially terrestrial (Kirkpatrick et al. 1998; Zhu et al. 2015). Arm-swinging is seen in juvenile *R. bieti* individuals, but not in adults (Wu 1993). The douc langur (*Pygathrix*) lives in Vietnam. They are largely quadrupedal but have been observed to brachiate with relatively high frequency (Byron and Covert 2004). The proboscis monkey (*Nasalis*) lives in Indonesia in riverine environments and sleeps along marginal river environments. They are entirely arboreal, with leaping as a large component of their locomotor repertoire, but also have been observed arm-swinging (Su and Jablonski 2009) and will occasionally swim across rivers. The Simakobu monkey (*Simias*) is found only on islands off of Sumatra. Little is known about their locomotor behavior; other than that, it is arboreal and leaps less than other colobines (Su and Jablonski 2009).

## Hominoids

Modern apes are largely restricted to the tropical forests of Africa and Asia. Each living ape group has their own unique suite of locomotor behaviors but shows a number of similarities (with modern humans being the exception). No modern ape is strictly an above branch palmigrade quadruped.

The Asian apes (orangutans and gibbons) are strictly arboreal and utilize suspensory (below-branch) forms of locomotion. African apes (chimpanzees and gorillas) are partly arboreal and terrestrial, utilizing varying locomotor behaviors in the trees, but are knuckle-walkers when terrestrial. Despite their different locomotor behaviors, modern apes have largely similar postcranial features. They have, to varying degrees, long forelimbs and digits, a broad thorax with dorsally positioned scapulae, shorter and less flexible lower backs (great apes have three to four lumbar vertebrae, compared to seven for cercopithecoids), mobile wrist and shoulder joints and lack an external tail. Although these similarities might suggest homology among these features, there is increasing evidence that these are merely convergent features as adaptations to being large-bodied arboreal primates, although this is still controversial (e.g., Begun 2007; MacLatchy 2004; Ward 2007).

Gibbons (*Hoolock*, *Hylobates*, *Nomascus*) and siamangs (*Symphalangus*) are the smallest living apes and are found only in the tropical forests of Southeast Asia. Gibbons are brachiators *par excellence*. Unlike other primates that will cautiously arm-swing below branches, brachiation by gibbons includes an aerial phase, where neither hand is grasping a support (often called “richochetal brachiation” (Hunt 1991)). Thus, gibbons progress in an acrobatic, pendular below branch fashion. As adaptations for this, gibbons are highly derived from the typical monkey body plan. Gibbons have extremely long arms (IMI of ~130) and fingers and have highly flexible wrists and shoulders. Gibbons arms are so long that they walk bipedally when they are on the ground or on large branches. Unusually for hominoids, they cross between gaps in the canopy by leaping.

Orangutans (*Pongo*) are the largest strictly arboreal mammals and are found only on the islands of Borneo and Sumatra in Southeast Asia. Similar to gibbons, orangutans locomote in a below-branch manner but, because of their large size, do so in a slow, deliberate mode often called quadrumanus (literally, “four handed”) climbing. Orangutans will progress in the trees in an upright posture supported from above by their forelimbs and often below by their hind limbs. Their

extremely mobile fore- and hind limbs allow them to grasp multiple supports, such that an orangutan may be grasping four different branches simultaneously. Orangutans cross gaps in the canopy by bridging or “tree swaying,” where the animal (more commonly, males) will use their weight to sway a tree back and forth, until it is close enough to the neighboring tree for them to cross (Sugardjito 1982). Male orangutans often must descend a tree and terrestrially walk to the next, as small terminal branches cannot support their large size. Orangutans have long forelimbs and short hind limbs and have an IMI of ~140. Orangutans also have extremely long fingers, mobile fore- and hind limbs, and a short lower back.

Gorillas (*Gorilla*) are the largest primate; male eastern lowland gorillas have an average mass of 175 kg (Smith and Jungers 1997). Gorillas are restricted to the forests of central Africa. Lowland gorillas live in the tropical rainforests of central Africa, and mountain gorillas are found in the montane forests of Uganda and Democratic Republic of Congo. The locomotor repertoire of gorillas therefore depends on their habitat, although they are the most terrestrial of nonhuman apes. Mountain gorillas are almost entirely terrestrial, as large trees are sparse in montane forests. Lowland gorillas are more arboreal; however, the larger size of male gorillas mainly restricts them to the larger branches near the trunk, whereas female gorillas, which are roughly the size of male orangutans, utilize more of the forest canopy (Remis 1995). When terrestrial, gorillas are knuckle-walkers. Like other apes, gorillas have a short lumbar spine, broad thorax with dorsally positioned scapulae, and longer forelimbs than hind limbs (IMI of 117) but have shorter digits.

Humans’ closest living relatives are the common chimpanzee (*Pan troglodytes*) and the bonobo or pygmy chimpanzee (*Pan paniscus*). Chimpanzees’ habitats range from the dense rainforests of Central Africa to the more open woodlands in the east to Tanzania. Chimpanzees are partly arboreal and terrestrial. Terrestrial travel is largely done by knuckle-walking, like gorillas (Tuttle 1969). When arboreal, chimpanzees are less suspensory than Asian apes, but more so than gorillas (Doran 1996). Chimpanzees are

diverse in their arboreal locomotor behaviors. They knuckle-walk on large supports and vertically climb up tree trunks. They engage in some suspensory locomotion and will often “scramble” or “clamber,” progressing in an uneven fashion, where the limbs are grasping multiple supports while the trunk is upright or orthograde (Hunt 1992). Bonobos are restricted to tropical forests south of the Congo River in Central Africa. Bonobos are both more arboreal and suspensory than chimpanzees (Doran 1993) but are otherwise similar in their locomotor behavior. Both species will occasionally walk bipedally, usually while carrying objects. Chimpanzees have longer digits and limbs overall but a lower IMI (107) than gorillas. Like other great apes, chimpanzees also have a broad thorax, mobile shoulders, and short lower back.

Modern humans (*Homo sapiens*) are unique among primates, and indeed among mammals, for our form of upright terrestrial bipedality. Humans walk with the trunk balanced over the hips, knees, and feet. Humans are the only primate to travel entirely on their hind limbs, and our postcranial skeleton reflects this. Humans have an S-shaped spine with an inward curving (lordotic) lower back, placing the center of mass above the feet while standing upright. Humans have a wide pelvis, with the gluteal muscles positioned laterally instead of posteriorly, allowing them to stabilize the pelvis during walking. Humans have valgus (inwardly angled) knees, placing them below the center of mass. Humans are also the only primate without a grasping big toe and have feet with arches, which act as shock absorbers. This lack of an opposable big toe makes human arboreal activity awkward. While the selective pressures that lead to this shift in our locomotor behavior remain controversial, bipedality (along with our large brains and tool use, both which appear much later in the fossil record) has allowed humans to permanently inhabit every continent except Antarctica.

## Conclusion

With the notable exception of modern humans, the locomotor specializations of modern apes have

largely restricted them to increasingly narrow geographic niches in the tropical forests of Africa and Asia. In contrast, cercopithecoids are relatively generalized, which has allowed them to not only exploit tropical forests but also niches as varied as the deserts of Morocco, the mountainous grasslands of Ethiopia, and the temperate forests of Japan and the Himalayas. While this is certainly related to numerous behavioral and demographic factors, the more generalized locomotor behaviors and postcranial morphology of cercopithecoids have allowed them to better exploit more varied environments better than modern apes.

## Catarrhine Morphology

Dionisios Youlatos

Department of Zoology, School of Biology,  
Aristotle University of Thessaloniki,  
Thessaloniki, Macedonia, Greece

## Definition

All the Old World higher primates, including monkeys, apes, and humans

## Introduction

Catarrhine primates are the haplorhine [i.e., non-strepsirrhine (=lemuroids and lorisooids)]

anthropoids (i.e., non-tarsiers) of the Old World, and they represent the most diversified group of primates living today. They have obtained their name from the Greek words that describe the placement of the nostrils, which face downward (κάτω (kato) = down + ρίνα (rhina) = nose), as opposed to their sister group, the New World monkeys, or platyrrhines, which bear a broad nose with nostrils facing outward (πλατύς (platy) = broad + ρίνα (rhina) = nose). They are currently represented by almost 183 different species, consisting of the well-known and highly diversified African baboons, drills, guenons, and mangabeys; the Asian macaques, langurs, and odd-nosed leaf monkeys; the Asian gibbons, siamangs, and orangutans; the African gorillas, chimpanzees, bonobos, and cosmopolitan humans. Their body mass ranges from the 1.1 kg of the female Angolan talapoin monkey to the 175 kg of a male African eastern lowland gorilla. Extant catarrhines mainly range in the tropical, the subtropical, and, in many cases, the temperate areas of both Africa and Asia. Nevertheless, they are the sole living primates that are not confined to the tropics. Some species are actually found in higher temperate latitudes, as in northern Africa, central China, and central Japan. In all these areas, they inhabit a very wide variety of habitats: lowland and montane tropical forests, gallery forests, woodland and savanna interface, savannas, semi-arid environments, lowland and montane temperate forests, rocky habitats, as well as high montane snow-covered deciduous and coniferous mixed forests. Their diet varies considerably. Most of the species are herbivorous (i.e., feed on plant items), and they may rely mainly on fruit, or they may feed principally on leaves. On the other hand, many species are omnivorous (i.e., they feed on both plant and animal food items), supplementing their diet with small invertebrates (larvae, insects, arthropods, worms, etc.) or more rarely, small vertebrates (amphibians, lizards, birds, or small mammals). Finally, a few species, such as the chimpanzees and humans, include a considerable, but variable, carnivorous component to their alimentary preferences, by hunting larger mammalian prey. In terms of habitat use, catarrhines may be exclusively arboreal,

exploiting the highest levels of tree canopies; semiterrestrial, being at home in both trees and the ground; or primarily terrestrial, using the trees only during resting and, occasionally, feeding, or even at all! This large primate clade also displays some remarkable ways of traveling around their habitat. Up in the trees, many species engage in frequent arboreal and quadrupedal walk and run and habitual leaping in between tree peripheries, and some of them employ cautious arm swinging along arboreal pathways or a very fast more acrobatic arm swinging mode, known as brachiation. On the ground, most species travel through terrestrial quadrupedal walk and run, whereas the great apes may prefer knuckle walking, fist walking, as well as obligate bipedal walking (e.g., humans)! Compared to the other primate groups, catarrhines are exclusively diurnal, i.e., they limit their activities during the light hours and sleep when it is dark; there might be some exceptions to the rule, but this is an occasional and not usual habit. On the other hand, catarrhine diversity is also expressed in their social organization and life. Among catarrhines, almost all different modes of social life are encountered, from solitary species, where both males and females range individually, with the former possessing extensive home ranges that overlap with many of the latter, to different levels of gregariousness, where a variable number of individuals travel and feed together in groups. Very few species (especially among the Asian lesser apes) form stable pair bonds, with variable roles between males and females (e.g., mate guarding or infant carrying), or polyandrous groups, composed of a single reproducing male and several sexually active females, which form a sort of communal breeding system. On the other hand, many species live in polygynous groups, consisting of one adult reproductive male and several females with their offspring. Satellite males form all-male bands and may interact with the group in variable ways. However, most species actually live in multi-male multi-female groups, which include several reproductively active adult males, females, and the offspring, characterized by a complex network of social relationships. In some species (e.g., chimpanzees), these social groups are more fluid,

modifying the size and composition of the group depending on source availability and individual relationships. In this case, females and the offspring tend to travel and forage together in smaller groups, whereas groups of males roam separately. These subgroups may join in at particularly rich food sources or form more long-lasting groups during the period of abundant resource availability. Finally, other species (e.g., baboons, snub-nosed monkeys) form multilevel societies, composed of multiple one-male units, each made up of an adult male, several adult females, and their offspring which congregate into large groups of many individuals. This great variety of ecobehavioral adaptations is accompanied by an analogous diversity in cranial, dental, postcranial, and soft tissue morphology, which is important for differentiating the diverse radiations of the group. However, they all share some common morphological characters that distinguish them from other primate groups, such as the strepsirrhines, the tarsiers, and the New World monkeys. These common traits actually characterize the group, and the present chapter aims to briefly describe them.

## Catarrhine Origins

In order to trace down the morphological traits of catarrhines, it is important to understand their origins and closest relatives within the fossil record. The current fossil evidence demonstrates that the earliest representatives of the catarrhines first appeared in the Afro-Arabian geographical zone during the early Oligocene, some 29–32 million years ago (Ma). However, molecular evidence suggests that catarrhines may have a much earlier history, which may extend back into the middle Eocene, some 40–44 Ma (Chatterjee et al. 2009). Despite this incongruence, the early catarrhines, geographically restricted to Afro-Arabia, diversified into many different groups until the early Miocene, some 17–18 Ma, when they first migrated to Eurasia (Harrison 2013). These fossil groups include the propliopithecids from the early Oligocene (29–32 Ma) Fayum deposits in Egypt, the saadanioids from the late Oligocene (28–29 Ma) Harrat Al Ujayfa in western Saudi

Arabia, the dendropithecoids from several early Miocene (15–20 Ma) East African sites, and the pliopithecids from several early to late Miocene (18–7 Ma) Eurasian sites from Spain to China. Moreover, they include two other groups, the hominoids (apes and humans) and the cercopithecoids (Old World monkeys), which comprise all the currently living catarrhines. Despite their great diversity, all these groups share some cranial, dental, and postcranial features that are essential for their definition. The major ones are the absence of a lateral orbital fissure, a highly reduced postglenoid foramen, a tubular ectotympanic, a dental formula of 2.1.2.3 (with the reduction of the number of premolars to two in each half of the upper and lower jaws), an anteriormost premolar shaped as a simple tooth with a broad buccal surface, a posteriormost premolar always shaped as a semi-molariform tooth, relatively square upper molars, relatively broad lower molars that increase in size from m1 to m3, lack of a dorsal epitrochlear fossa on the distal humerus, and possession of a saddlelike carpometacarpal joint of the thumb (Harrison 2013). Through the millions of years of evolutionary radiations within the catarrhines, some of these features have been retained, while others have been modified and are diagnostic of the different groups.

## Major Cranial Characters

Catarrhines have inherited from their anthropoid ancestors a skull with a generally enlarged neurocranium and a relatively short snout (Fig. 1a). These morphological modifications are also associated with a relatively reduced internal nasal region, which is followed by a reduced number of nasal conchae, the narrow, curled, spongy bones that protrude from the nasal cavity walls and are responsible for regulating the air-flow through the nasal cavities. Moreover, the reduced function of the nasal passages and the associated decrease of the role of olfaction in more derived primates are further depicted by the shortening of the nasolacrimal duct, already in the haplorhines. In strepsirrhine primates the

nasolacrimal duct empties its contents into the anterior end of the nasal vestibule and contributes to the moistness of the wet rhinarium (nose) and open lips, which are an integral part of the role of the vomeronasal organ in functional olfaction. In contrast, haplorhine primates developed a dry rhinarium coupled with closed hairy lips. In platyrrhines, this nose is relatively broad and the nostrils are wide and directed laterally (outward), whereas catarrhines possess quite narrow nostrils that tend to face ventrally (downward), a significant external character that is responsible for their name. The new arrangement of the dry rhinarium and closed lip forced the nasolacrimal duct to shorten, to be redirected more vertically, and to open more caudally than in the nasal vestibule. This rearrangement is very likely associated with the reduced emphasis on vomeronasal-based olfaction and is further suggested by the relatively small accessory olfactory bulb in anthropoids

(i.e., tarsiers and platyrrhines), and its subsequent loss, as well as that of the vomeronasal organ in catarrhines (Rossie and Smith 2007). The short snout and the relatively reduced nasal bones appear to have compelled the positioning of the lacrimal bone within the orbit, rather than external to it on the snout, a character that catarrhines have further inherited from their anthropoid ancestors.

In catarrhines, as in all anthropoids, the orbits, the bony sockets where the eyes lie, tend to face forward in conjunction with their well-developed stereoscopic vision (Fig. 1a). However, in catarrhines the anterior margins of the orbits have slightly migrated posteriorly and are located at the level of the molars (Fig. 1a), instead of the level of canine-postcanine junction, the condition of ancestral anthropoids. The important role of vision in higher primates is further suggested by the bony rearrangements that surround the eyes. Whereas in strepsirrhines, the eyes are laterally

**Catarrhine Morphology, Fig. 1** Skull of macaque showing the most important cranial characters of catarrhines: **a** short snout, placement of the orbits (*dashed*

*line*); **b** frontal bone-sphenoid bone junction; **c** enlarged canines, two upper and lower premolars; **d** tubular tympanic bone

encircled by a postorbital bar, a strut composed of the frontal and zygomatic bones, the eyes of anthropoids, and therefore catarrhines demonstrate a completely different condition. Thus, the frontal, zygomatic, and sphenoid bones expand to form a bony plane that surrounds the eye latero-caudally and separates it from the temporal fossa behind, a condition known as postorbital closure (Fig. 1a, b). In this way, the eye lies protected within a bony cup, which presumably isolates the orbital content from the stresses imposed by the chewing muscles, acting at the level of the temporal fossa (Heesy et al. 2005). The walls and floor of the orbits are separated by several fissures that contribute to the transmission of specific nerves and allow the passage of vessels and veins. Most primates are characterized by three fissures, the superior, the inferior, and the lateral one. Anthropoid primates have retained distinctive superior and inferior fissures, but have significantly reduced the lateral one. Catarrhines are unique in having completely lost the lateral orbital fissure (Harrison 2013).

The increased role of vision is also implied by the anatomy of the eyes in higher primates. In contrast to prosimians, which possess an extra reflecting inner layer, known as tapetum lucidum, that enhances night vision but reduces visual acuity, anthropoids lack this reflecting layer. Instead, they bear a specialized area called the retinal fovea on the posterior surface of their eyeball. In this area, the light-sensitive cells are packed extremely close together, allowing very good visual acuity. This acuity is further correlated with the relative size of the optic foramen that allows the connection between the eye and the brain via the optic nerve (Kay and Kirk 2000). All catarrhines are characterized by full color vision similar to that found in most humans, with three types of color-sensitive cells (cones), each one sensitive to a different part of the visual spectrum (Jacobs 2009).

On the external surface of the lateral side of the skull, just behind (caudally) the closed eye socket, merge the frontal, parietal, zygomatic, and sphenoid bones. Catarrhines are distinctive from all other primates, in that the frontal bone contacts the sphenoid bone and separates the zygomatic

bone anteriorly from the parietal bone posteriorly (Fig. 1b; Fleagle 2013). In the other anthropoid group (the New World platyrrhines), the zygomatic contacts the parietal and separates the frontal bone dorsally from the sphenoid bone ventrally.

The middle ear of primates is characterized by the presence of the auditory bulla, a thin cup of bony tissue that derives from the petrous part of the temporal bone and covers the inferior surface of the middle ear. Moreover, the spatial relationship between auditory bulla and the tympanic ring is considerably variable and is important for distinguishing in between different primate groups. Among higher primates (anthropoids), the tympanic ring is attached (fused) to the lateral wall of the auditory bulla. But in catarrhines, the tympanic ring not only is attached to the wall of the bulla but further extends laterally to form a bony tube, the external auditory meatus (Fig. 1d; Harrison 2013).

Another important diagnostic catarrhine cranial character lies on the ventrolateral surface of the skull, just posterior to the glenoid facet where the mandible articulates with the skull. There lies the postglenoid foramen, a passage to where leads the sulcus of the petrosquamosal sinus and accommodates the joint anterior and middle venous plexuses from the middle cranial fossa, as well as the veins from the posterior cranial fossa. Lower primates and tarsiers are characterized by a large foramen, whereas catarrhines, as a group, possess a reduced postglenoid foramen, forcing the principal drainage of the brain to obtain a more posterior exit (Kay et al. 2008).

In the foremost part of the skull, the two premaxillary bones are completely fused together early in life, and therefore there is complete closure of the interpremaxillary suture, a cranial character which is defining for catarrhines. In an analogous manner, the two halves of the mandible are also fused together in their foremost part. This feature has been inherited from the anthropoid ancestors of catarrhines and seems to be functionally associated with the development of vertical lower incisors in anthropoids, in contrast to the more procumbent ones found in prosimians (Fleagle 2013). However, detailed ontogenetic

analyses have provided evidence that in ancestral catarrhines, this mandibular fusion is actually based either exclusively or majorly on the superior transverse torus over the inferior transverse torus of the mandible. Functionally, this condition probably minimizes stresses associated with lateral transverse bending and dorsoventral shear of the mandibular symphysis during mastication (Panagiotopoulou and Cobb 2011).

## Major Dental Characters

The dental characters in primates, as in other mammals as well, are usually the features that are very characteristic for each major primate radiation. All catarrhines possess two incisors in each quadrant. They are never procumbent, as in prosimian primates, and this is a trait that characterizes all anthropoids. The canine teeth are usually large with a large root and are always larger and usually taller in height than the incisors (Fig. 1c). These teeth have been further differentiated in being strongly bilaterally compressed with a single mesial groove and sexually dimorphic in Old World monkeys. A major feature that distinguishes catarrhine primates from their platyrrhine relatives is the number of premolars on each quadrant. Catarrhines only possess two premolars, in contrast to the three premolars of New World monkeys. This leads to a dental formula of 2.1.2.3 (Fig. 1c). The morphology of the anteriormost premolar is quite distinctive, as it is often a simple tooth with a broad and high buccal surface that sharpens the upper canine. On the other hand, the posteriormost premolar is always a semi-molariform tooth. Catarrhines have retained three upper and lower molars. The upper molars are usually relatively square shaped with low and conical cusps. Usually, the lower molars are relatively broad, with moderately high and conical cusps and low and rounded crests, and increase in size from the first toward the third.

## Major Postcranial Characters

As in all anthropoids, the forelimbs and the hind limbs are more similar in length. This is the case

for platyrrhines, but in catarrhines there is a great variability which is related to the very divergent locomotor modes that this very diverse group has adopted. Thus, cercopithecoids (Old World monkeys) in general possess more or less equally long forelimbs and hind limbs. There are however some exceptions to the rule, such as some Asian odd-nosed colobines, which apparently engage frequently in forelimb suspensory locomotion. The pattern is a somewhat different in hominoids, and especially the living ones, where the forelimbs are longer than the hind limbs. This is not very evident in chimpanzees and bonobos, or even gorillas, but orangutans and gibbons and siamangs, which frequently use cautious and fast forelimb suspensory locomotion, respectively, possess quite long forelimbs compared to their hind limbs. Humans are the only hominoid primates with particularly long hind limbs in relation to their obligate bipedalism.

All catarrhines lack grooming claws and possess flat nails on all digits. Catarrhines are characterized by a saddle-shaped carpometacarpal joint of the thumb (Fig. 2a; Harrison 2013). This arrangement, between the trapezium bone of the carpus and the first metacarpal, allows a wide range of rotatory mobility, as well as abduction and adduction of the thumb contributing to thumb opposition and enabling powerful grasping capacity (Lewis 1989).

On the distal side of the anterior surface of the humerus, most primates are characterized by the presence of a variably wide foramen, called the humeral entepicondylar foramen, which accommodates the median nerve and the brachial artery. Although its presence is not that consistent in some primate groups, catarrhines are characterized among primates, by the complete lack of this foramen (Fig. 2b). The deep fascia and the tight skin at the distal humerus already protect the median nerve so the entepicondylar foramen may not be necessary. Moreover, this absence in catarrhine primates has been associated with increased forearm abduction in association with brachiating locomotion, has been considered as a by-product of the narrowing of the humeral distal articular facet and the reduction and posterior placement of the medial epicondyle, or even related to

**Catarrhine Morphology, Fig. 2** Skeletal features of catarrhines (macaque): **a** saddle-shaped joint between the trapezoid wrist bone and the first metacarpal bone of the thumb; **b** absence of entepicondylar foramen

stochastic events, and was subsequently related to some functional purposes (Garbino and de Aquino 2016).

At the ischial area of the body, all Old World monkeys, the gibbons, and the siamangs have thickened layers of tissue overlaying expansions of the hip bones (ischial tuberosities). These ischial prominences on each side beneath the anal area are provided with horny epidermal thickenings creating a pair of well-developed sitting pads. These pads are commonly known as ischial callosities (Pocock 1925). Only, the Asian and African great apes and humans lack these callosities. In the females these pads are separated in the middle line, and the opening of the vulva is typically situated inferiorly between them. In males, where there is no such obstacle, the pair of callosities sometimes tends to fuse completely across the middle line below the anus, although in the majority of the cases they retain their distinctness. Their functional importance is still debated, but they are probably related to the frequent use of seated postures on slender branches during both resting and sleeping, as well as during feeding, as they provide a wide area that contributes to comfortable and stable sitting (McGraw 2017).

Living catarrhines represent a highly diversified group of primates. However, in general the living catarrhines are among the largest of living

primates. Their body mass ranges from the 1.1 kg of female talapoin to the 175 kg of male gorillas. Definitely, they are on average much larger than the representatives of their sister group, the platyrrhines. These latter usually range between 100 g of pygmy marmosets and 13 kg of the largest atelid monkeys. Moreover, living catarrhines are much more terrestrial than other groups of prosimians and monkeys, as many species, such as some baboons, some mangabeys, many guenons, some langurs, gorillas, and humans, make extensive to exclusive use of the ground (Fleagle 2013). Another distinguishing feature indicating the great diversity of catarrhines is the large proportion of specialized folivorous (leaf eating) species. Supplementing the dietary regime with leaves is a relatively widespread habit among primates, especially during periods of fruit scarcity. However, catarrhines evolved whole radiations that morphologically and behaviorally adapted to regular folivory, such as the colobus monkeys of Africa and the langurs (leaf monkeys) of Asia, all belonging to the subfamily Colobinae of the cercopithecoidea.

## Conclusion

All these cranial, dental, and postcranial characters render catarrhines one of the most diverse

groups of primates. This diversity is also demonstrated in the variety of characters that further differentiate between the different adaptive radiations, such as the cercopithecines and colobines within the cercopithecoids and the lesser and great apes within the hominoids. All these morphological characters are beyond the scope of this chapter. Despite this variety, the characters presented here are those that unite all catarrhines as a unique group of single origin that has conquered and shaped the world.

## Catarrhine Navigation

Rahel Noser

Cognitive Ethology Lab, German Primate Center, Göttingen, Germany

## Introduction

Primates are different from other animals in several ways: they possess hands with at least one flat nail instead of paws and claws, their big toes are opposable (except humans), and they have relatively large brains. Such broad anatomical differences also exist within the primates, and this has been the reason why taxonomists have set catarrhines apart from all other primates. Most prominently, catarrhines are the only primates that have dry noses with the nostrils pointing forward or downward, just like our human noses. Catarrhine species share additional anatomical features, but it is not easy to see how these should affect their navigational abilities and set them apart from other primate clades.

A factor that may be important, however, is the fact that catarrhines are generally larger than other primates and therefore have higher energy requirements. Unlike other animals with very large bodies such as elephants and horses, they cannot obtain more energy by extending feeding times into the night. So, what are their options?

Leaf-eating monkeys (Colobinae) have solved this problem by evolving a specially adapted stomach supporting bacterial colonies that allow them to digest the cellulose in their diet of leaves, unripe fruits, and seeds. Feeding on such abundant foods has the advantage that food is generally available and nearby (Byrne 2015).

However, other large-bodied catarrhines rely on particularly energy-rich ripe fruits. Unfortunately, fruit is unreliable, because it is often available only at specific places in space during short time periods per year. Some trees fruit at irregular time intervals and do not necessarily synchronize their fruiting state with conspecifics. To make things worse, some catarrhines complement their fruit diet with a wide variety of additional foods located at other places their home ranges. Some live in large groups, comprising up to 100 members, and some inhabit areas with pronounced seasonal changes in food occurrence. To find enough and adequate food for all these mouths, these groups require large home ranges that cannot be overlooked from one location, nor walked in a single day. To deal with the unreliability of their food, these catarrhine primates need to be experts in remembering spatial locations, food types, fruiting periods, and experienced navigators to travel among them efficiently. According to the “cognitive map hypothesis” (sometimes called the “ecological intelligence hypothesis”), some primates have evolved large brains to overcome this specific set of problems, permitting advanced cognitive operations (Milton 1981, 1988). This puts a broad group of catarrhines into the spotlight: the cheek-pouch monkeys (baboons and macaques), guenons, gibbons, orangutans, gorillas, chimpanzees, and humans, who are all relatively large-bodied, live in large groups in large home ranges, and rely on ripe fruit, at least to some degree.

However, how do catarrhine primates navigate large-scale space? Do they really find their food by means of more sophisticated cognitive operations than do other animals? How do they memorize feeding events? How do they represent spatial relations among different places? And – most importantly – how can we find out?

## The Concept of Cognitive Maps

During their observations of rats running complex mazes, Tolman and Honzik (1930) noted that animals learn about space just by exploration, even if they do not experience any positive or negative events therein. To investigate how quickly rats learn to recover a food reward at a specific out-of-sight maze location, they formed three rat groups. Each group obtained a different treatment: individuals of group A found the reward from the first trial onward, while the rats in group B were given the opportunity to explore the maze without reward for a couple of trials, before being rewarded during the next couple of trials. Group C was a control group. They found that group B rats – the ones who had been allowed to explore the maze – learned to recover the reward much quicker than group A. Obviously, they had formed a memory of the layout of the maze during exploration in the absence of food and were able to apply it to revisit the goal location quickly when needed. Tolman (1948) claimed that the brain, rather than forming infinite numbers of associations between stimuli and responses, filtered important spatial stimuli and put them into context with others, forming an integrated “inner image” or “mental representation” of space that encoded several events and some spatial properties between them. He called this mental construct a “cognitive map” and stated that such maps could be relatively simple and strip-like or broad and comprehensive, containing large numbers of locations where important events had taken place and the spatial relations between them. He pointed out that the degree of comprehensiveness of this map decided how flexible an animal could navigate space.

Psychologists found Tolman’s concept useful and refined his ideas. They distinguished route maps (sometimes also called network maps) from Euclidean maps (synonymous of survey maps or vector maps) to describe the mental representations that animals have of spatial locations and events (Fig. 1). Route maps are thought to represent the paths through an environment and nodes of intersection. They contain sequences of memorized landmarks and knowledge about what

**Catarrhine Navigation,**

**Fig. 1** Behavioral consequences of using a cognitive route map and a Euclidean map. Euclidean maps allow animals to take novel shortcuts to out-of-sight goals

to do at each landmark, perhaps in the form “big rock with dead log, go left; field of thorn bushes, go straight ahead; etc.” (Byrne 2000). Theoretically, such a route map ties individuals to relatively narrow standard paths, beyond which they get lost. A route map can represent a single familiar route or constitute in a network of many routes and intersections that extend over an animal’s entire home range, connecting a large number of important locations with each other.

Euclidean maps, in contrast, are thought to resemble a mental image similar to what a bird can see when flying over an area, a “view from above,” from which all important locations and their spatial relations are visible at once. Euclidean maps are encoding distance and direction information among all important resources and consequently allow animals to flexibly take least-effort routes between any two resource places. The behavioral manifestation used to distinguish whether cognitive maps are based on route or Euclidean information is shortcutting: only a Euclidean map allows an animal to take a novel shortcut to reach a destination.

Neuroscientists use the concepts of egocentric (or self-referenced) versus allocentric (or map-based) representation to describe the neuronal processes involved in mammal navigation. This concept is closely related to the mental map

concept, but it is important to understand their fundamental differences. According to this view, animals using an egocentric navigational mechanism are thought to locate objects in space with reference to themselves by means of “path integration.” Path integration requires active body movement which allows to constantly integrate distances traveled and turns taken. It enables an animal to return to the starting point, for example, the nest, in a straight route at any time. During allocentric navigation, an animal is thought to use the spatial relationships among landmarks to determine its own position in the environment. Thereby, distances between landmarks are thought to be estimated by means of path integration. According to this concept, the egocentric and allocentric systems always work hand in hand in many mammal species, with the availability of landmarks determining which one currently dominates. In humans, it has been suggested that mechanisms of formation of episodic and semantic memory have evolved from egocentric and allocentric navigation in the physical world, as the brain networks that support these navigation mechanisms and memory formation extensively overlap (Buzsaki and Moser 2013).

The remainder of this entry will refer to the concepts of route maps and Euclidean maps, as they formed the basis for many studies on the

cognitive aspects of nonhuman catarrhine primate navigation in large-scale space.

## Integrated Memories of Location and Food Type

Many catarrhine primates have a long-term memory for several food locations. For example, mangabeys living in the African rain forests approach distant, non-visible trees where they have previously fed on ripe fruit more frequently and faster than they approach trees without fruits (Janmaat et al. 2006). Before encountering spatially predictable economical food or water sources, baboons inhabiting the sub-Saharan savannas and semideserts usually travel rapidly and in a linear manner over large distances. Sometimes, they start speeding up their travel shortly before reaching important places where they spend some time feeding or drinking, but with the fruit trees or water holes still out of sight. In contrast, more indirect and slower travel precedes encounters with less predictable and less economical foods. This has been interpreted as evidence that they aim at specifically important places (Sigg and Stolba 1981; Kummer 1997).

Thus, if catarrhine primates approach memorized places in a goal-directed manner, do they expect specific rewards at these locations? Menzel (1991) investigated this question in free-ranging Japanese macaques (*Macaca fuscata*). He walked with these animals and from time to time placed either a piece naturally occurring but currently out-of-season akebi fruit or a piece of equally preferred chocolate on the ground. As soon as an individual ate the food, he recorded start location and subsequent behavior. What the macaques did after finding akebi fruit was different from what they did after discovering chocolate. Akebi finders stared upward, walked to and inspected distant trees containing akebi vines. In contrast, chocolate finders returned to the precise location of their finds hours later, sometimes on the following day, to visually and manually inspect the location. Control animals who found nothing did neither enter akebi vines nor go back to the start location. Thus, macaques who found a known

food – akebi – relied on the specific spatial long-term memories generated by multiple previous encounters with that food type. By doing so, they would have found many more items of the same food – had akebi only been available. Macaques who found a novel food type – chocolate – lacked any spatial memories of additional “chocolate trees” and were forced to base their search on a memory generated by that single recent find.

## Anticipation of Food Type

At what point along a foraging trip do these memories become available? Do baboons recall a food source ahead of them when they start speeding up their travel? Does a chimpanzee recall a fig tree containing sweet fruit when waking up in the morning? Do catarrhines think of future visits to distant locations before they fall asleep?

Noser and Byrne (2007a) noted that departure times from the sleeping site of a baboon group living in a South African woodland savanna depended on the fruit type that was first consumed in the mornings. Generally, these baboons took up foraging sooner on hot days compared to colder ones, obviously to forage during the cooler mornings and to have enough time to rest in the cool shade during noon. However, departure times were particularly early when they breakfasted on out-of-sight mountain fig fruit (*Ficus glumosa*). In contrast, when they breakfasted on out-of-sight marula fruit (*Sclerocarya birrea*), they left the sleeping cliff significantly later. What caused these varying departure times? Figs were confined to a couple of small trees, and many baboon groups fiercely competed for access to them, as only a single group could occupy and deplete a tree at a time. In contrast, ripe marula fruit occurred in quantities that supported the entire baboon population in the area for weeks, in addition to a wide variety of additional mammalian and bird foragers. Thus, Noser and Byrne (2007a) proposed the ability of anticipating breakfast type soon after waking up to be a cognitive tool to buffer competition: only those baboons who

arrive early at the fig trees are able to obtain fig fruit that had freshly ripened overnight.

This idea was confirmed in chimpanzees (*Pan troglodytes*) living in the Tai rain forest in Ivory Coast (Janmaat et al. 2014). Similar to the baboons, these chimpanzees departed earlier from their nest when breakfasting on figs and later when breakfasting on other fruit. Moreover, while baboons usually reuse a small number of safe trees or cliffs to sleep in at night, chimpanzees build a new nest on a different tree every evening. As a consequence, distances and directions to the breakfast fig trees alter from morning to morning, making the task of arriving early at the fig trees more difficult. Nevertheless, the chimpanzees managed to arrive early at the fig trees: when the nests were located further away from the fig trees, the chimps left their nests earlier, while they left later when the fig trees were situated at shorter distances. In line with Noser and Byrne (2007a), Janmaat et al. (2014) argued that the chimps did so to outcompete other chimpanzees, birds, or squirrels, who also like to feed on newly ripened figs.

Thus, catarrhine cognitive maps encode several integrated memories for locations in large-scale space where different food types had been consumed. These memories can be formed through a single foraging episode and allow for flexible decisions about travel onset that affect the likelihood to successful encounters with anticipated food. It is not known to date whether non-human catarrhine primates anticipate more than a single future event.

## Travel Among Several Locations

If the cognitive maps of catarrhines contain several locations in space, how efficiently do they travel among them? Or in terms of the “traveling salesman (or salesperson) problem”: given the positions of several places on a scaled map, which is the routing that will take a monkey or ape to all of these locations covering the shortest possible overall distance? The answer to this general problem is not simple, because overall travel distance is to a large extent affected by the order in which goals are visited. Places may differ in

reward or other intrinsic features, so that many past experiences must be compared. How do catarrhine primates behave in the context of this sort of problems?

In his seminal study, Menzel (1973) investigated how captive chimpanzees navigate among several food sources. For this purpose, an experimenter carried around one of six young chimpanzees and allowed him or her to watch a second experimenter hide some fruit in each of 18 places in a large outdoor enclosure. All six chimpanzees were then simultaneously released and allowed to forage in the outdoor enclosure. Time when each piece of fruit was found (or the corresponding place was rechecked) and the identity of the animal involved were subsequently recorded for 1 h. The informed animals found a total of 12.5 fruit pieces per trial; the ignorant ones found only 0.21 pieces. Importantly, the informed chimpanzees did not follow the routes the experimenter had taken when hiding the fruit, but they ran from one place to the next, no matter how distant this place was situated from the previous one. They did not minimize overall travel distance, but kept it fairly short. Thus, captive chimpanzees who forage under the eyes of hungry conspecifics are not particularly good at any attempt to solve the traveling salesman problem.

## Route Maps Versus Euclidean Maps

Altmann and Altmann (1973) were the first to notice that baboons (*Papio cynocephalus*) that forage in their natural habitats forage on the basis of an extensive spatial knowledge about food and water sources and use a cognitive map.

Sigg and Stolba (1981) studied the cognitive maps of a group of baboons (*Papio hamadryas*) in detail. This group lived in a semidesert in Ethiopia and traveled extraordinarily large distances each day (up to 20 km). They carefully mapped travel routes and feeding and drinking locations. When superimposing these maps, it became evident that the baboons neither used narrow standard routes predicted by a simple, strip-like route map nor did they flexibly take least-distance routes between any two resources as predicted by a Euclidean

map. Instead, they often traveled along standard “street segments,” by definition 150 m wide and at least 500 m long, which they flexibly combined each day so that their location could never be predicted. The relative large width of the street segments suggests that the baboons recognized distal landmarks or scenes and used them as reference points along remembered routes.

While these results still suggested an impressively detailed route map, this study also highlighted a major problem that researchers generally face when studying animals in the wild. How can we know whether a given travel route is novel? A route that we record only once in a 2-year field study can nevertheless be a well-known route that the animals regularly used before we watched. On the other hand, the fact that we do not find any evidence for Euclidean mental maps in routine foraging in the wild is per se not evidence against them. Perhaps, the baboons do use Euclidean knowledge, but it becomes evident only in particular situations.

In an attempt to overcome these problems, Noser and Byrne (2007b) studied how the presence of competitors altered space use of a small baboon group (*Papio ursinus*, Fig. 2). These baboons normally approached important locations in a goal-directed way and from different angles, confirming that they possess a detailed route map. Because their daily routine was rather constant over the months, it was possible to predict their goals with high confidence. However, group encounters altered the baboons’ routine. Noser and Byrne’s idea was that Euclidean knowledge – if present at all – should allow this small group to flexibly alter space use and take detours around others.

They found that this was indeed the case when the baboons could use topological structures as reference points: on and in an area of around 1,000 m of a hill, the small group reoriented to alternative fruiting areas or water holes situated at large distances, and they took large detours of several hundred meters that were out of sight of the initial routes. However, in a poorly structured plain area of their home range, space use after group encounters was very inflexible: when becoming aware of a nearby baboon group, the

focal group often remained on their initial routes, movement came to a halt, and the animals spent up to 60 min waiting on the spot until the others disappeared, before travel was resumed. Detours did occur in this area, but they were so small that visual contact with the initial routes could always be retained. Impressively, a whole day journey was abandoned on one occasion, causing the group to return to the sleeping site in the morning to feed on low-quality food until dusk. Thus, baboons expertly use landmarks present at distances up to a km in relation to which they organize travel. However, they do not use Euclidean knowledge about space to avoid group encounters, but rely on route knowledge. Evidence from other catarrhine species does not contradict this notion.

## Large-Scale Navigation in Humans

But how about humans? Navigating the sea has been of particular importance for humans for many centuries. In some cultures, this gave rise to the invention and spread of a variety of navigational instruments such as the sextant, the compass, the chronometer, and the GPS, allowing measurement of angles, directions, distances, locations, and trajectories. In other cultures, however, navigation remained instrument-free until very recently. Navigation techniques of the Pacific islanders, who traditionally made long canoe voyages with a high degree of accuracy, are a particularly interesting case.

In Polynesia, instrument-free navigation between distant islands is challenging because the islands are too far apart to be seen from each other. The sea lacks any stable landmarks to guide the trips from one island to the next. Experienced navigators were highly esteemed in their societies for their ability to memorize and combine large numbers of cues and their complex interrelations that guided their trips. They used sequences of stars that disappeared below the horizon in the desired direction, the sun’s path on the water, current wind directions, but also minute observations of long wavelength swells produced by distant winds and those of smaller waves interacting

**Catarrhine Navigation, Fig. 2** Baboons abort their journey (a) or take small detours (b) as a response to encountering larger baboon groups (large arrow) in areas of their home range where rich topological structures are lacking. Reorientation (c, d) and large detours (not shown) take place only in the vicinity of rich topological structures (a hill). (c) After leaving the sleeping site, the baboons slowly headed SW, while another group was repeatedly calling from that direction. After a period of silence, they took up rapid travel into a SSW direction, where their main

water hole and important berry bushes were situated. They encountered the other group (large arrow) and turned back in a large circle. They then reoriented NW, where another large feeding area was situated. (d) To reach this area, they traveled a route that they usually used counterclockwise, from the NW feeding area back to the sleeping site. Dotted lines: contour lines. Circles and squares: locations where movement came to a halt for feeding (dots) or resting (squares). Foraging journeys (black lines) start at the sleeping site (small gray area)

with the swells and with land, of the location and form of clouds in the sky, and of the occurrence and behavior of sea animals. Because these cues were available only during a fraction of the journeys and sometimes entirely absent, integrating multiple cues created a “toolkit for navigation” for which redundancy was a critical feature (Huth 2016). Thus, rather than a Euclidean map that represented distances and directions among the islands, navigators used an extensive knowledge of sequences of external cues and landmarks that confirmed their actual positions along their journeys.

Indeed, the traditional “rebbelibs” or stick charts (Fig. 3) crafted by Micronesian navigators constitute a beautiful example of the kind of cognitive maps that humans can build. These charts are composed of wooden sticks that represent swell and wave patterns of the sea. Small shells attached to the support sticks represented the locations of the islands. Because they are constructed on the basis of personal experiences at specific locations, rather than on a “bird’s perspective,” each navigator constructed its own, unique rebbelib that looked different from those of his fellow navigators. However, rebbelibs represent

**Catarrhine Navigation, Fig. 3** “Rebbelib” stick chart used by the Marshallese to navigate the Pacific Ocean by canoe, indicating sailing directions for atolls and islands. Seashells depict the atoll and island locations. Each *straight stick* represents regular currents or waves around the low-lying atolls, while the *curved sticks* depict ocean swells (Source: National Library of Australia, MAP RM 4388)

integrated information about the relative spatial locations of the islands that are, in fact, spread out across several hundred miles, with body movement information that navigators had collected when lying on the canoe floor and sensing the rhythmic seas (Huth 2016). Thus, although these stick charts may not encode exact distances and directions, they constitute an allocentric representation of the spatial relations between important locations.

While only few individuals excelled in navigation among the Pacific islands, Maguire et al. (2000, 2006) confirmed that the neuronal basis of navigation is remarkably flexible in humans. London taxi drivers, who flexibly use their extensive knowledge of thousands of streets, places of interest, and their interconnectivity on a daily basis, show larger amounts of gray matter in the posterior hippocampi – one of the areas in the brain involved in navigation – than both a control group who do not professionally drive and London bus drivers who follow predetermined routes. The increase in neurological tissue occurs during the time when taxi drivers undergo extensive training to obtain their license, and this is also

the time – of course – when spatial knowledge dramatically increases. In contrast, trainees who fail exam and a control group who does not go through training at all do not show these structural and knowledge changes (Woollett and Maguire 2011).

Another important feature of human navigational ability is its large variation, spanning from the impressive abilities of Polynesian navigators and London taxi drivers to a significant number of healthy humans with severely impaired navigational abilities (Iaria and Barton 2010). Whether such differences exist in nonhuman catarrhine species remains open to future research.

## Conclusions

Catarrhine primates use space in a way suggesting that they possess a cognitive map that encodes information about several routes to important locations and content at these locations. Because they anticipate the content of their next goal, nonhuman catarrhines can act to positively alter future outcomes. However, there is no solid evidence that they anticipate more than a single goal at a time, and they do not minimize travel among multiple locations, but keep the overall distance short. To date, there is broad evidence for the usage of route-based representations of space. Only humans additionally routinely construct symbolic maps that encode information about the relations of objects and events as if viewed from a bird’s perspective. In contrast, evidence that nonhuman catarrhines are able to take novel shortcuts, a characteristic property of a Euclidean mental map, has remained feeble.

## Definition

The Catarrhini are an Infraorder of the Order Primates that includes the Old World monkeys, apes, and humans. Sensory systems are the ways in which animals perceive and experience the world around them.

## Introduction

All living things have evolved sensory modalities to take in information about their environment, allowing them to react in appropriate ways to best enhance their survival and reproduction. In mammals, these modalities are often discussed as the five senses (i.e., sight, hearing, smell, taste, and touch). However, the mammalian sensory system also includes rarely considered senses, such as proprioception and other senses internal

to the body. Below, we discuss each of these modalities and how catarrhines use them.

## The Five Senses

### Vision

Primates rely primarily on visual information for many important daily activities, including evaluating predation threats, navigating interactions with conspecifics, and during foraging bouts. Among the primates, some have developed a specialized ability for color vision (trichromacy) which is unique in comparison to other eutherian mammals, who are thought to be either dichromatic or monochromatic. However, not all primates are consistently trichromatic; routine color vision evolved only in the catarrhines and in one other taxa (New World howler monkeys). All catarrhine species are considered routine trichromats, where both males and females are capable of color vision (Lucas et al. 2003). More specifically, this means that all catarrhines have the ability to distinguish between lights of different spectral composition regardless of brightness, and further, between red and green coloration (Surridge et al. 2003). This is in contrast to most platyrrhines (New World monkeys excluding howlers) and all strepsirrhines (lemurs and lorises), where trichromacy is generally a polymorphic trait and only females are capable of trichromacy.

Physiologically, trichromacy in primates is achieved through the actions of photoreceptor cells, called cone cells, in the retina of the eye. These cone cells generate responses that are then compared with each other by neural mechanisms to generate color signals. Some of this processing of color cues is thought to occur in the primary visual cortex (V1), but it is not yet clear to what extent. Cone cells house photopigments; in primates, the primary photopigment is opsin. Importantly, these cone cells differ in their spectral sensitivity, or more simply, the wavelengths of light they are sensitive to. Most mammals possess only two kinds of cone receptors, one of which responds to short-wavelength light of about 430 nm and is conventionally known as the

S cone and another that responds to long-wavelength light of about 560 nm and is conventionally known as the L cone. The combination of only two cones renders most nonprimate mammals dichromatic. However, in catarrhines, trichromacy is possible due to an additional cone receptor in the eyes that is maximally sensitive to middle-wavelength light of about 530 nm, which is conventionally known as the M cone. This additional cone arose early in the catarrhine lineage through a duplication in the gene for the long-wavelength cone that caused it to diversify into two kinds of cones with differences in peak sensitivities. More specifically, routinely dichromat primates possess a single gene coding for L cone pigments and M cone pigments, which is located on the X chromosome. However, in catarrhines, this gene was duplicated resulting in separate L and M cone pigments with differing spectral sensitivities. The signals produced by this additional M cone are then compared by a second neural subsystem: the relatively more modern “red-green” mechanism compares L with M cone signals, while an evolutionarily older “blue-yellow” mechanism compares S cone signals with both L and M cone signals combined. Because most platyrrhine primates do not have this duplicated M/L gene, males are thus genetically restricted to receiving only either an M or L opsin pigment on their X chromosome in addition to an S opsin (which is encoded by an autosomal gene). This limits them to dichromacy. Thus, among platyrrhine primates other than howlers, only heterozygous females can express trichromacy, but both male and female catarrhine primates are trichromatic.

In catarrhines, trichromacy is thought to have evolved to aid in foraging, either in the selection of ripe fruits or young leaves. This is because younger and more preferred leaves tend to be redder in color than more mature (and thus less preferred) leaves, which become green at mature stages of growth. The additional M cone enables all catarrhines to see young leaves among mature foliage, as the phylogenetically newer L/M subsystem allows for the detection of brighter, more colorful targets amidst a contrasting green

background. In addition, ripe fruits shift to a variety of colors during maturation, causing them to stand out as well among unripe fruits and leaves. Therefore, for catarrhines foraging for either young leaves or ripe fruits, consistent color signals are thought to be a more reliable strategy in finding food than other cues such as lighting or form. This is simply because lighting and form cues can be much more variable and thus less reliable than color cues. Further, the evolution of full trichromatic vision appears to coincide with a deterioration of the sense of smell, suggesting an increased reliance on such visual coloration cues. It has also been proposed that trichromacy can be useful in detecting intraspecific signals (Allen 1879). For example, ovulating females of some species display distinctive red sexual swells, males may signal high testosterone with red skin ornaments, and many colobine infants have bright neonatal coats in orange hues.

Another primate visual adaptation is the evolution of orbital convergence. Forward-facing eyes allow for binocular vision leading to excellent depth perception. This is important because early primates spent much of their time in trees. Binocular vision could therefore have allowed tree-dwelling primates to accurately judge distances when jumping between trees and branches. Additionally, the presence of a fovea centralis amplifies the effect of increased depth perception in haplorrhines as well as that of trichromacy in the catarrhines. The fovea centralis is a tiny pit located in the central retina that enables these primates to see sharp details and color and to have excellent central vision. In the fovea, light is able to fall directly onto the cones to produce maximum visual acuity. The fovea is thought to have evolved in stem haplorrhines and is a visual feature characteristic of both catarrhine and platyrrhine primates (Williams et al. 2010).

### Audition

In general, primate vocalizations serve to convey information about internal motivational states and the surrounding environment, including conspecifics and inanimate objects (Hauser 1993). These vocalizations are produced through movements of

the lungs, larynx, and the supralaryngeal vocal tract (Ghazanfar 2010). Hearing is known to be a multimodal sensory ability in primates, in that the auditory cortex integrates information from multiple sensory avenues. This includes the integration of visual information, such as when one links visual and auditory communication signals (e.g., matching facial expressions to congruent vocal expressions). The speed and accuracy of the visual orienting reflex is also an example of the integration of auditory and visual areas in the brain. Interestingly, auditory areas also appear to integrate tactile information, for example integrating the kinesthetic feedback from one's own speech movements with heard speech. In early primates, increased visual field overlap may have been associated with selection for increased sound localization abilities (Dominy et al. 2004). This is because in other animals, increased visual acuity positively correlates with a well-developed ability to localize a sound in space. More specifically, in other mammals sound localization abilities correlate with the width of the field of best vision, in that species with narrow fields of best vision (i.e., a fovea) have better abilities to localize sound than mammals with broad fields of best vision (Heffner 2004). Importantly, this trend holds for primates; the two species for which visual acuity and field of best vision are both known are relatively good sound localizers. As others have proposed, it may be that good sound localization acuity was evolutionary selected for its usefulness in directing vision (Heffner 2004). Primates are also similar to other mammals in that smaller species are capable of hearing relatively higher frequencies than larger species, but all primates appear to have relatively good low-frequency hearing; humans in particular have highly restricted high-frequency hearing.

Regarding the auditory sense, there are distinctive anatomical features that separate the catarrhine auditory sense from that of other primates. For example, all catarrhines have evolved a complete bony canal that leads from the ear drum to the external auditory meatus (outer ear hole) and is visible on the outside of the skull. This bony canal is called the ectotympanic tube. The

ectotympanic tube is formed by the ectotympanic bone, which consists of both a bony part and an external cartilaginous part. Put simply, this tube connects the tympanic membrane to the external ear. Tarsiers have also evolved a bony ectotympanic tube, but New World monkeys and prosimians have not (though in many species, a tube made up of cartilage is present). In regards to function, the ectotympanic tube has been proposed to be an adaption to reduce the amount of noise produced during mastication (Fricano and DeLeon 2016).

The ability to produce and comprehend speech is perhaps the most unique catarrhine capability but is restricted to only one extant species: humans. Physiologically, nonhuman primates are constrained in their ability to produce language by their anatomy and neural mechanisms. However, the neural mechanisms available in nonhuman primate brains are likely to have contributed to the evolution of human speech, in that human language appears to have built on mechanisms and structures available in nonhuman primate brains. Language processing is multimodal and is carried out in part by several different regions of the brain, including the well-identified Broca's and Wernicke's areas. These areas are well known to be crucial in the production of language (Broca's area) and in the comprehension of language (Wernicke's area). The only nonhuman primates thought to have a well-developed frontal lobe containing a functional homologue to one of these areas are catarrhines. In catarrhine primates, the anatomical and functional homologue to Broca's area is thought to be located in a section of the monkey premotor cortex (Fogassi and Ferrari 2007). Interestingly, this area houses audiovisual mirror neurons that discharge when a monkey performs an action and hears the corresponding sound (e.g., tearing paper and hearing a rip). This area and related structures may have evolved to exercise control over orofacial actions related to communication, but in humans may have come to control actions related to speech as well. Thus, the production and comprehension of language is a complex ability limited to humans but has clear roots in the anatomy and neural structures that currently exist in nonhuman primates.

## Olfaction

Relative to other mammals and other primates, the catarrhine sense of smell is reduced. Mammals usually have two systems to take in scent information from airborne molecules, the main olfactory system, which detects volatile odorants, and the accessory olfactory system, primarily made up by the vomeronasal organ (VNO), which detects nonvolatile odorants of heavier molecular weights (e.g., pheromones) (Dominy et al. 2004). However, catarrhines have lost the use of the VNO and the olfactory bulb that processes scent information is small relative to other primates. It has been hypothesized that the importance of trichromatic color vision in catarrhines may have relaxed the need for sensitive smell. Old World monkeys, apes, and especially humans have all lost the functioning of many of their olfactory receptor genes, which have been replaced by pseudogenes. Trichromatic New World howler monkeys show a similar pattern but this high rate of loss in functional olfactory receptor genes is not seen in dichromatic species or those polymorphic for color vision (Gilad et al. 2004). The timing of loss of the VNO in the catarrhine lineage also corresponds roughly with the evolution of trichromacy 25–40 million years ago. Catarrhines are notable for the degree to which color is used as signals of dominance and fertility, so it is possible that visual information that was available with routine trichromacy made information on pheromones gathered from the VNO redundant (Liman 2006). Even without a VNO, catarrhines are still known to detect some phenomenal cues but appear to do this with the main olfactory system.

## Gustation

It is appropriate to discuss taste immediately after smell, since the two are intricately linked when animals are selecting and experiencing resources. Gustation actually occurs when the stereochemical structure of a substance being tasted is recognized by taste bud sensory cells on the tongue, causing gustatory nerve fibers to fire, transmitting impulses to the brain of different taste sensations. However, what people normally think of as the "taste" of something is actually the interaction of a suite of sensory perceptions, including most

strongly the odor and reaction of taste receptors, but also the feeling of it touching the tongue, any irritation to the mouth caused by compounds within it, and perception of the temperature (Hladik and Simmen 1996). Prior to more intensive research, it was thought that primates could recognize four basic tastes, including salt, sweet, bitter, and sour. The taste of umami, which includes glutamic acid and its derivatives was added to this list later (Kawamura and Kare 1987). The notion of basic tastes is still often used but research on taste physiology has shown that most of the taste bud sensory cells located on the tongue will react to several substances though they may have higher affinities for certain ones (Faurion 1987). This suggests that taste sensations are more of a continuum rather than a set of basic tastes. Research on several primate species has shown that tasting abilities cluster in closely related taxa and differ when species are less related. In accordance with this, human and chimpanzee tasting abilities are very similar but some minor differences have been found between apes and Old World monkeys (Hellekant et al. 1997).

Taste perceptions, preferences and aversions have clear evolutionary importance. For instance, bitter, sour, and astringent substances elicit a strong taste aversion in primates and many of these (e.g., alkaloids, tannins, saponins, terpenes) are toxic. The three other “basic tastes,” sweet, salty, and umami often indicate nutritive content (Liman 2006). Primates show a correlation between body size and the threshold in the ability to detect sucrose and fructose, important sugars found in fruit. Larger primates have lower thresholds and thus a greater ability to detect minute concentrations of sugars. This may be due to larger animals having a greater area of lingual mucosa on the tongue leading to better taste acuity. This ability likely allows these larger primates to find a wide array of food stuffs palatable, helping them maintain their body size (Hladik and Simmen 1996).

### Somatosensation

The sense of touch can be defined as somatosensory perception that allows an organism to take in information on pressure, vibrations, itches, pain,

and temperature. Sometimes included in somatosensation are also the muscular and visceral sensations that can be perceived from inside the body (interoception). Primates appear to have a strong awareness of their internal homeostatic afferent activity and if the physiological condition of any part of the body is not normal this will be perceived by autonomic motor control and communicated to the brain with sensations such as thirst, hunger, discomfort, or pain (Craig 2003).

Different types of cutaneous receptors take in various forms of tactile information. Touch is perceived with rapidly adapting cutaneous mechanoreceptors like Meissner corpuscles, hair follicle receptors, and free nerve endings. Pressure is more likely to be detected with slow adapting cutaneous mechanoreceptors like Merkel corpuscles. Temperature is perceived with thermoreceptors and pain and itch are perceived by nociceptors (Mada 2000). The anthropoid primates, a classification that includes all catarrhines, are particularly notable for the density of cutaneous mechanoreceptors on the hand (Dominy et al. 2004). The hand is the most important sensory organ for tactile stimulus in catarrhines and almost all species have fine motor control, long fingers, an opposable or semiopposable thumb, and nails instead of claws, allowing the sensitive finger tips to be exposed. Mechanoreceptors for touch are especially located on the glabrous skin of the palm and palmar aspect of the fingers, where different types of sensory endings are found in the thick epidermal layer that forms patterns of ridges and grooves (Vallbo and Johansson 1984). Parts of the brain in the thalamus and cortex are primarily responsible for taking in somatosensory information.

Touch plays an extremely important role in communication in catarrhines, allowing information transfer through tactile means. Different types of touch are ascribed meaning but this may be changed or tempered depending on the situation and the duration or intensity of the touch (Hertenstein et al. 2006). For instance, a kick may be aggressive but if it is done lightly in a playful situation the meaning can be changed completely. The most developed sensory modality for infant catarrhines at birth is touch and it has

been shown to regulate infant psychological states and aid in normal biological and social development. In humans, physical contact between mothers and infants is key in bond formation, with more frequent and nurturing contact from the mother leading to more secure children later. As the other senses become keener into adulthood, touch does not have the over-riding importance that it has for infants; however, it is still vital for people in many interactions, in particular compliance, power relations, intimacy, and hedonic perception (Hertenstein et al. 2006).

One of the main tactile behaviors seen in catarrhines (in both nonhumans and humans) is grooming. While grooming does have a hygienic function, it is also very important in bonding and status maintenance. In Old World monkeys and apes, individuals generally spend more time grooming those that are kin or closer to them in dominance rank and grooming tends to go up the hierarchy with more dominant individuals receiving more than subordinates (Schino 2001). Grooming has also been shown to relieve stress, aid in reconciliation following aggression, and build bonds that may later lead two individuals to support one another in aggressive encounters (Dunbar 2010).

## The Neglected Sense

### Proprioception

In order for animals to control their movements, they must be aware of where their body is in space. Three systems are primarily used to do this, the felt position of the body (proprioception or the kinesthetic sense), visual cues regarding where the body (and each limb) is located, and tactile cues of body parts touching substrates. All of this information is processed in the premotor cortex in catarrhines. In particular, proprioception has been discussed in four broad sets of sensory perceptions: the sense of position and movement, the sense of tension, the sense of effort or heaviness, and the sense of balance (equilibrioception). Different but related mechanisms appear to be used for these four sets of perceptions (Gandevia 1996). Tendon organs allow a sense of tension and

the central nervous system is responsible for the sense of effort. Sensing of position and movement is done through muscle spindles and receptors in skin and joints but also through the vestibular system, which additionally provides the sense of balance. The vestibular system in the inner ear contains three semicircular canals that sense rotational movement and two otolith organs, called the utricle and saccule, that sense acceleration. Research has shown that the vestibular system has extensive convergence with many other sensory systems, acquiring constant signals from the eyes, muscles, joints, and skin, making it extremely important in everyday function for animals (Angelaki and Cullen 2008).

## Conclusion

Compared to primates that retain more primitive ancestral characteristics, catarrhine sensory systems are most notable for routine trichromatic color vision, a reduction in the olfactory sense, and the importance of the hand as a sensory organ.

## Definition

A category is a knowledge/memory structure that summarizes an animal's understanding of perceptually variable but environmentally equivalent objects – especially relevant ecological natural kinds (e.g., blossoms for hummingbirds). Through category learning, animals come to behave consistently/adaptively toward these kinds. Animals have possessed a categorization capacity for hundreds of millions of years. Vervet monkeys (*Chlorocebus pygerythrus*) even employ eagle calls to alert conspecifics to dangerous category members. These calls “name” a member of Category Eagle, functioning like lexical items or words. Because categorization is an essential cognitive capacity, it has been a sharp focus of comparative research. Theory in animal categorization tries to explain the representational content of animals' categories and the process by which objects are perceived and categorized. Extensive research furthers this mission of psychological explanation. However, categorization raises difficult issues for comparative psychologists relating to learning, memory, generalization, abstraction, and symbolism.

## Introduction

Sections “[Theories in Animal Categorization](#),” “[Tasks in Animal Categorization Research](#),” and “[Stimuli in Animal Categorization Research](#)” in this entry survey the influential theories in animal categorization, the structure of categorization tasks, and the diverse stimuli employed. Section “[Prototypes and Exemplars in Animal Categorization Research](#)” explains why one theory – prototype theory – carries especially heavy weight when explaining animals’ categorization. Section “[What Kinds Are Natural?](#)” provides an evolutionary context for section “[Prototypes and Exemplars in Animal Categorization Research](#)” conclusion, paying attention to natural kinds in the environment. Section “[The Search for Rules and Hypotheses in Animal Categorization Research](#)” asks whether animals may learn categories through active hypothesis testing, and whether they then categorize by following the dimensional rules that are those crystallized hypotheses. Section “[The Search for Relational Concepts in Animal Categorization](#)” considers animals’ higher-level categories – the conceptual-relational categories like same or different. This section considers whether animals can transcend category groupings based on perceptual similarity, and the nature of the psychological processes that let them do so. Animals’ use of abstract concepts raises intriguing questions about the roots of human cognition and about the affordance that language offers to abstraction and symbolism. Finally, section “[A Broader Synthesis](#)” integrates across the entry to show why animal categorization research suggests a transformative theoretical synthesis.

## Theories in Animal Categorization

The literature is usefully organized around three dominant theoretical perspectives.

*Prototype theory.* Influential research by Rosch and others (e.g., Rosch and Mervis 1975) formed the basis for prototype theory. This idea is that minds average their experiences with categories, like predator eagles, to construct the central tendency or category prototype. This prototype could

be the mental content of the animal’s category. Then, as a processing matter, the animal could compare new items – new possible threats – to the prototype and include them in the category if similar enough. It will become clear that this theory has merit in explaining important aspects of animal categorization.

However, it presents problems, too. First, having a platonic ideal of eagle in mind does not tell you the category’s useful generalization radius. Where does eagleness stop, and vultureness begin? Baby vervet monkeys illustrate this problem by sometimes making tiny eagle calls for airplanes! Second, prototype averaging requires the brain algorithms by which the essence of many experienced exemplars can be extracted. These averaging algorithms are not trivial. Third, though some categories can be based in prototypes, others are logical (e.g., exclusive-or categories), ad hoc (e.g., items to try to save in a flood), or random (e.g., who is in my foraging group today). So, even if prototype theory has merit, categorization theory should leave room for the possibility that animals and humans might have different categorization processes for managing different categories.

*Exemplar theory.* Exemplar theory is diametrically opposed to prototype theory. This idea is that animals store specific exemplars as separate and individual memories, refer new items to these multiple stored category members, and include the new items as members if they are – in summed total – similar enough to the stored exemplars. Thus, exemplar theory envisions the vervet monkey’s Eagle category as a slide carousel of many eagle memories.

Exemplar theory presents problems, too. First, memory-capacity limits may fail the animal given thousands of experiences with common categories. Second, the resolving power of mind may not let the animal hold separate the thousands of experienced eagles. The exemplars may melt together in memory like chocolate drops in an excellent cookie, creating de facto a Rosch prototype representation. Third, the animal may be taken by the eagle while it is still working through its Eagle Rolodex to decide if it should flee!

However, exemplar theory has one remarkable aspect that explains its long dominance in the

literature. It potentially makes the psychology of categorization parsimonious and unitary, with only one exemplar storage/comparison process to understand. In essence, all categories could be deemed equivalent, solvable by just memorizing the exemplars to refer back to. Thus, one might not need to suppose species differences in categorization, or task differences in categorization strategies, or different brain circuits for managing different category tasks. It is an important question whether this parsimonious account is also the psychologically true account. Comparative science must pursue the latter.

*Classical or rule theory.* Classical Concept Theory predated both prototype and exemplar theory. This idea was that categories might be defined by criterial (100%-diagnostic) attributes for category membership (e.g., triangle-3 sides; dog-barks). This idea figured prominently in Bruner's work on concept formation (Bruner et al. 1956). Child psycholinguists favored this theory because they thought that young children might progressively carve up their conceptual worlds appropriately by adding criterial features to make finer conceptual distinctions, for example, animal (living), then bird (living-flying), and then parrot (living-flying-squawking). Classical Theory faced problems, too. First, many natural-kind categories may not have criterial features (e.g., voiceless dogs and hairless cats are still categorizable). Second, Classical Theory expects that all category members should be equally good category members because they all have the defining attributes. But this is patently false. Everyone agrees that golden retrievers are prototypical dogs, while dachshunds – on the fringes of the category – barely cling to dogness by their stubby paws. Third, there is no guarantee that animal species have the cognitive capacities that lie behind hypothesis testing for criterial features or systematic rule application in category tasks.

A range of research exploring these theoretical perspectives will be covered in sections “[Prototypes and Exemplars in Animal Categorization Research](#),” “[What Kinds Are Natural?](#),” and “[The Search for Rules and Hypotheses in Animal Categorization Research](#).”

## Tasks in Animal Categorization Research

The tasks of animal categorization have the familiar character of discrimination-learning tasks. A stimulus is presented, then the animal identifies it by choosing among several responses (e.g., left or right operant levers, abstract icons A or B). During learning, of course, the assigned identification response may vary as the animal proceeds unevenly toward concept mastery. Feedback is delivered following the animal's response on each trial – perhaps a food reward for a correct category-identification response, perhaps a tri-allell time-out period for an incorrect response.

However, discrimination and category tasks are crucially different in one way. Discrimination tasks commonly present two contrasting stimuli (two tonal pitches, two shades of red) – so that one stimulus maps to each response. This is the nature of psychophysical procedures, threshold assessments, sensory-sensitivity titrations, and generalization/habituation paradigms. In contrast, category tasks commonly have a many-to-one structure. There may be many members of Category A and B in these tasks, and the members will be perceptibly different, to varying degrees of dissimilarity. The animal must find some way to generalize inclusively among stimuli within categories while still discriminating exclusively across categories. This is what it means to say that a category is a psychological or behavioral equivalence class. The animal's psychological understanding of Category A must be broad enough to encompass the range and extent of its stimuli. Then, the animal can behave equivalently toward those stimuli, making the same identification response to all. Category tasks give the comparative researcher an extraordinary window on the kinds of generalizing and synthesizing processes that animals are able to apply, and about the kinds of generalization glues that a species may not be able to supply.

Given this general task logic, the researcher can make many different decisions to suit the particular question being asked.

*Category size.* The researcher can create categories that contain few or many category members (e.g., Smith et al. 2004; compared to Smith

et al. 2008). This choice has consequences. Large exemplar sets may challenge exemplar memory and push processing toward prototype averaging. Small exemplar sets may push processing toward exemplar memorization. After all, John, Paul, George, and Ringo are easily individually remembered – this category needs no prototype.

*Within-category similarity.* The researcher can decide how similar the members of a category will be to one another. A tightly coherent cloud of exemplars in psychological space may defeat individuated exemplar memories and encourage prototype averaging. A far-flung set of disparate exemplars may affect strategy in the opposite way. Readers are warned by this discussion that the category structure chosen for research is an important aspect of design that affects performance and theoretical interpretation. Caution: The fix may be in.

*Between-category dissimilarity.* Likewise, the researcher can decide how separate and dissimilar the two sets of instances, for Category A and Category B, will be from each other. Here, too, it is useful to imagine the A and B instances as two clouds of points in a Cartesian space. The two exemplar clouds can be close together, far apart, or even overlapping/colliding. The latter case will create confusable categories that are difficult to learn. It is also possible that this difficulty may distort the learning situation, so that the organism's normal processes of category learning become impossible and helplessness strategies ensue instead. This visualization of exemplar clouds is not just figurative. In many formal categorization models, this assumption is explicitly made mathematically, and the ideas of proximity, distance, and so forth are taken deeply seriously. Homa and colleagues (e.g., Homa et al. 1979) showed that, as category learning progresses, the category clouds condense and self-tighten within each cloud (because the organism's developing understanding of the categories draws the instances closer together), while the clouds of instances move apart from each other in similarity space (because the organism more clearly understands the distinguishing contrasts among them).

*Structural ratio.* The previous two aspects of category structure can be combined and frequently are. For example, one can take the degree of

within-category similarity displayed by Category A and Category B and divide this by the degree of between-category similarity, which can be measured as the degree of similarity between Category A and B items. In the generic situation, the numerator of this ratio would be large, the denominator small, producing a high structural ratio indicative of well-structured, learnable categories. In contrast, a category structure presenting a structural ratio near 1.0 would be extremely difficult, because items would be as much like opposing category members as they are like their own category members. This kind of category task was common in early cognitive research on categorization, and this presented serious interpretative issues.

*Linear separability.* This last aspect of category structure is technical but still supports an important intuition. For linearly separable categories, the following is true: There is an additive weighting of the stimulus dimensions in the task, such that, using that weighting, all the members of Category A would be called A and all the members of Category B would be called B. Geometrically, with two stimulus dimensions, there would be a straight line through perceptual space that successfully partitions all the As from all the Bs. In a three-dimensional space, this partitioning boundary would be a plane.

The intuition is simple. If the members of your family generally have the same eyes, the same hair, the same nose, and the same hair color, your family could be linearly separable from other sets of siblings – even if not everybody has everything exactly the same. But if there is a goose in the duck family, this family would be nonlinearly separable relative to another duck-duck-duck family. There would be no way to cleanly (geometrically, mathematically) partition the family groups. Important theoretical conclusions have emerged from tasks involving nonlinearly separable categories containing exceptions of just this kind.

## Stimuli in Animal Categorization Research

Important considerations also attend the stimuli chosen for animal categorization research.

*The ecological dimension.* One important choice dimension is the naturalness of the stimulus materials. For example, in one of the most venerable animal categorization experiments – Herrnstein et al. (1976) – researchers presented pigeons with slides of real-world scenes that contained tree elements (trunks, branches, and leaves) or did not. Pigeons showed clear mastery of some kind of “Tree” category. Their category knowledge clearly generalized when new tree/not tree slide sets were swapped in.

Wasserman et al. (1988), in another influential example, presented pigeons with realistic images of chairs, cats, cars, or flowers, giving the pigeons four response keys for identifying the category of the presented image. Pigeons became robustly accurate in performance and generalized successfully to new instances. Moreover, the pigeons’ success with chairs and cars makes plain that birds are capable of learning human artifact categories, not only ecologically relevant (even genetically ingrained) categories like Tree.

Using ecological materials has the strength that it may tap into animals’ truest, most natural categorization capacities, that is, the processes they would use and the representations they would develop when learning the natural-kind categories of their own world. This makes the use of these stimulus materials highly ecologically valid.

Using ecological materials has the weakness, though, that there is no control over the dimensions of stimulus variation, the relative salience of perceptual dimensions, and the within-and-between-category metrics defining the category structures. For example, it is not known what is varying in the hundreds of tree slides, or even what pigeons may be perceiving therein. And one does not know how perceptually coherent or tightly knit the categories are. So, ecological materials are rich, valid, and intriguing but present important unknowables.

At the other pole, away from naturalness, researchers have also used stimulus materials that are clearly highly artificial. For example, Cook and Smith (2006) used beach-ball stimuli with many colored pie-slice sectors, not like any natural kind animals experience. Likewise,

Smith et al. (2008) used nine-dimensional random-polygon shapes, equally artificial and nonecological. The weakness is that these materials may not elicit from animals their most natural and ecological category-learning strategies. But the compensating strength is that one can know, as Cook and Smith knew, exactly the dimensions of variation in their stimuli, the ranges of variation, the balanced salience among the dimensions, the similarity separation between opposing categories, and even potentially the allocation of attention that a pigeon chooses across the stimulus dimensions. Likewise, in Smith et al. (2008), a fully developed psychophysics of perception and similarity lay behind the use of those random-polygon categories. Here, ecological validity was traded off for experimental control and psychophysical precision. Clearly, the researcher must choose the strength they pursue, the trade-off they choose, and the sacrifice they make.

*Generating category-member variability.* Researchers also make different choices about the ways in which stimuli will vary within a category. One very common approach is to have categories defined along many dichotomous features. So, for example, in Cook and Smith (2006), different color sectors of the stimulus disks could be red-green, yellow-brown, blue-gray, and so forth. This means that each feature can only take on two values, an artificial, nonecological feature of the stimuli. It also means that many stimuli will have features shared identically with members of the opposing category, for example, the disk in Category A with the gray sector may have an important feature shared with B category members. The possible effects of this must be clearly understood by researchers. Others have used richer and more graded dimensional variation, so that Category A stimuli might have dimensional values 1, 2, 3, and the Category B stimuli 4, 5, 6. Jitsumori (e.g., 1996) has used a richer stimulus-generation methodology like this to elegant effect. Finally, as shown below, others have used more complex statistical-distortion methods to create stimuli that are carefully controlled variations of a central prototype and graded in psychophysical similarity to it.

## Prototypes and Exemplars in Animal Categorization Research

Extensive research has tempered the early dominance of exemplar theory toward the present consensus that prototype abstraction plays the dominant role in animals' categorization. In meaningful synergy, this consensus has reached across to refashion the human literature. In this way, animal participants have been extraordinary behavioral ambassadors to cognitive science.

**Prototype abstraction.** For example, Smith et al. (2008) used a method of category construction in which category members were created at different distortion levels from an originating, central prototype. Grounded in stimulus-distortion techniques with a 50-year history in experimental psychology, prototypical, highly typical, untypical, and unrelated polygon shapes were generated. The first three of these item types composed a prototype-centered, family-resemblance category. The last item type should be rejected from category membership. These stimuli are illustrated in Fig. 1.

Smith et al. (2008) let macaques (*Macaca mulatta*) learn these categories. The open circles in Fig. 2 show how often a monkey endorsed different item types into the category. He maximally endorsed the prototype into the category,

**Categorization, Fig. 1** A dot-distortion category. *Note.* The originating prototype (P), low-level distortions (L), high-level distortions (H), and unrelated shapes (R) from top to bottom. This is a family-resemblance category with category typicality decreasing from the prototype outward. (Adapted from "Prototype Abstraction by Monkeys (*Macaca mulatta*)," by J. D. Smith, J. S. Redford, and S. M. Haas, 2008, *Journal of Experimental Psychology: General*, 137, p. 391. Copyright 2008 by the American Psychological Association. Reprinted with permission)

and category endorsements declined from there. Smith et al. used standard modeling approaches to emulate prototype-based and exemplar-based minds learning these categories. The exemplar model assumed that monkeys refer to-be-categorized items to multiple, memorized separate instances. The prototype model assumed that monkeys refer items to the prototype average derived from their exemplar experience. The models were controlled and matched but for this representational assumption.

The exemplar model (Es) failed to capture monkeys' performance. It sharply underpredicted monkeys' performance on the most typical items. These modeling errors are essentially disqualifying given the formal sophistication in this literature. That macaques exceeded those predictions shows that their minds are not referring items to collections of individuated exemplars. In contrast, the prototype model (Ps) fit monkeys' performance so perfectly that these symbols are barely discernible. Something like a prototype was the macaque's cognitive

**Categorization, Fig. 2** The proportion of times a macaque endorsed items as a category member. *Note.* As shown in Fig. 1, decreasing typicality was a function of increasing shape distortion from the prototype. Exemplar (E) and prototype (P) models fit the macaque's performance. These models differed in assuming many memorized exemplars as cognitive reference points in categorization or a single, central, prototype reference point. (Adapted from "Prototype Abstraction by Monkeys (*Macaca mulatta*)," by J. D. Smith, J. S. Redford, and S. M. Haas, 2008, *Journal of Experimental Psychology: General*, 137, p. 395. Copyright 2008 by the American Psychological Association. Reprinted with permission)

reference point, a conclusion reinforced by other studies (e.g., Jitsumori 1996). Monkeys were blending their exemplar experience into something like a prototype reference standard by which they categorized. This experiment shows conclusively that exemplar processing is insufficient to explain all of what categorizing animals do, though still it may account for some of what they do.

*Exemplar theory's failure.* This experiment also lets one explain why exemplar theory's fundamental representational/processing assumption can be falsified. Exemplar theory's idea is that categorizers store exemplars as separate memory traces spread out like droplets in a cloud in the mind's psychological space. Then test items are compared to these multiple traces. It is simply impossible for a test item to be highly similar to all the comparative standards for categorization – it will always be near to some but far from others. Therefore, the overall category-belongingness signal will inevitably be weakened, reducing performance predictions for typical items, which the exemplar model showed but the macaques did not. The remarkable thing is that the exemplar model's failure here is inherent, inexorable, and incurable. In contrast, if the animal averages experience into a prototype, then a test item can be indefinitely close to the prototype in

psychological space, and the performance expectation can be indefinitely high. This the prototype model predicted, and the monkeys confirmed.

*Prototype-exception categories.* Prototype-exception tasks also allow researchers to contrast prototype and exemplar processing (Fig. 3). The eight shapes on the left (right) are all reinforced as Category As (Bs), though the second-row stimuli seem to belong to the opposing category. If monkeys assume prototype-based categories based in perceptual family resemblance, they will have difficulty mastering exception items, because they will continue to group those exceptions with the prototype of the OPPOSING category. But if monkeys simply memorize the exemplars and associate correct responses to them, they should be able to master the exceptions as well (just as you could learn the membership of rock group Beatles, even if they were John, Paul, George, and Cardi B).

Figure 4 shows macaques' performance (Smith et al. 2010). The macaques persistently erred on the exception items, even performing then below chance. They showed minimal capacity to memorize and respond appropriately to exceptions. If their natural threat categories had exceptions as here (e.g., eagles in sheep clothing), it would be a fitness disaster (for the monkeys, not the eagles).

**Categorization, Fig. 3** A prototype-exception category task. *Note.* The left and right stimulus groupings represent two categories. Six stimuli in each case are variations of that category's central prototype. Two exception stimuli are variations on the theme of the opposing prototype. (From "Stages of Category Learning in Monkeys

(*Macaca mulatta*) and Humans (*Homo sapiens*)," by J. D. Smith, W. P. Chapman, and J. S. Redford, 2010, *Journal of Experimental Psychology: Animal Behavior Processes*, 36, p. 43. Copyright 2010 by the American Psychological Association. Reprinted with permission)

Rather, the monkeys (sensibly) assumed that they were confronting two perceptually coherent, well behaved, family-resemblance categories. By this strategy, of course, cross-categorizing the exceptions is perfectly correct. Humans show similar phenomena (Smith and Minda 1998). Section “What Kinds Are Natural?” considers whether possibly the natural world is sensible in the same way.

Figure 4 shows that monkeys somewhat mastered the exceptions by experiment’s end. This is why the literature does not exclude exemplar theory from consideration, but rather emphasizes that animals may have different processes available for managing different kinds of category problems. This mixed perspective presently seems best for understanding animal and human categorization.

*The phylogenetic depth of prototypes.* Cook and Smith (2006) took a broader evolutionary

perspective toward these phenomena. They tested prototype-exception tasks with an avian species (pigeons – *Columba livia*). The birds classified prototypical, typical, and exceptional disk-sector stimuli as belonging to Category A or B. Pigeons made the same family-resemblance assumption that macaques and humans do. They cross-categorized the exceptions, producing high error rates on those items. And pigeons’ performance was not fit by an exemplar-based model, because pigeons performed too well on the prototype items and too poorly on the exceptions. These prediction errors are as expected given the discussion above. But pigeons showed the same late transition to exemplar memorization as monkeys. Again, there was a late-breaking exemplar capacity, after hundreds of trials, to finally somewhat learn/memorize exceptions.

*Isolating the exemplar process.* A third productive approach in this area has been to eliminate

**Categorization, Fig. 4** Performance by three macaques in the category task of Smith et al. (2010). Note. Curves T and E show the proportion of correct responses made to the typical and exception items that were illustrated in Fig. 3. (From “Stages of Category Learning in Monkeys

(*Macaca mulatta*) and Humans (*Homo sapiens*),” by J. D. Smith, W. P. Chapman, and J. S. Redford, 2010, *Journal of Experimental Psychology: Animal Behavior Processes*, 36, p. 48. Copyright 2010 by the American Psychological Association. Reprinted with permission)

from the tested categories any sense of family-resemblance cohesiveness or prototypy, so that this form of processing is ruled out and the need for exemplar processing stands alone. An exclusive-or (XOR) category task can achieve this process isolation (Fig. 5). Here, the Category A instances would “average” into the central point of perceptual space – but so would the two Category B instances. Moreover, in this case, one must place perfectly opposite stimuli with zero shared features into same category. Prototype averaging is doubly pointless. But exemplar processing would be fostered, because there are only two distinctive and memorable instances of each category to learn.

Smith et al. (2011) gave macaques two-, three-, and four-dimensional XOR tasks. Figure 5 illustrates the two-dimensional task – the others are more elaborate. Monkeys found these tasks stripped of prototypy very difficult. They made thousands of errors on the way to low levels of terminal performance. Thus, even facing the sharp and exclusive need to memorize exemplars, macaques showed a minimal capacity to do so.

**Categorization, Fig. 5** Illustrating an XOR category task. *Note.* Stimuli vary in the patterning of the leftward semicircle and the shading of the rightward semicircle. Stimuli with no shared features must be categorized together. Stimuli with shared features must not be categorized together. Prototype-averaging processes cannot work in this task. Exemplar memorization is recommended instead

In this respect, comparative and human research have a strong resonance. Early on, exemplar theory was dominant partly because researchers relied on poorly structured categories as already defined, including XOR categories. Thus, they defeated prototype processing, while fostering the memorization of exemplars within small categories. And yet, about half of humans in these early experiments were never able to reach the established learning criterion. Humans display an exemplar-processing deficit in category learning just like animals do. Exemplar processing’s role in the learning and processing of category information thus must be delimited carefully and narrowly. It is likely that it plays only a supporting role relative to prototype processing.

This area of the literature can be summarized. Animals make a strong family-resemblance assumption in category learning, assuming they will encounter perceptually coherent classes of mutually similar objects (i.e., linearly separable as defined above), and usefully organized around a category prototype. Their exemplar-processing capacity in category learning is far weaker and empirically shy – recruited weakly toward poor performance, recruited only late in testing after dogged training, and recruited poorly even given the ideal circumstances focusing on exemplar processing and only allowing exemplar processing. Far from the dominant theoretical status that exemplar theory once enjoyed, a mixed-process theoretical perspective toward category learning appears to be mandatory based on current research, with something like prototype processing playing the dominant role.

### What Kinds Are Natural?

Why, though, do animals have a frail exemplar capacity in categorization? Why do they commit strongly to prototypes in categorization? These questions raise the larger question of how animal minds *should* be organized – optimally and toward fitness – toward category learning.

This issue has received theoretical attention. Briscoe and Feldman (2011) noted that storing individual exemplars might store information too

specifically and at the wrong grain for generalizing to new items. After all, for a bat to store in detail every eaten mosquito is useless – those mosquitos will never need categorizing again. Here, a generalized representation might be better. However, they also noted that in certain situations high-specificity exemplar storage might be valuable.

Brooks (1978) explained why organisms might have occasional need for prototype-averaging and exemplar-memorizing processes. There are times – as in coping with an alpha conspecific – when exemplars must be understood individualistically. There are thinly populated categories (e.g., patriotic songs) wherein individual exemplars stay individuated. But there are densely packed categories, too, for which a generic representation may be cognitively economical. In fact, the research just presented shows how different category structures can press category processing toward prototypes or exemplars. Thus, it would not be surprising if animals and humans potentially brought multiple and alternative strategies to the table during category learning.

Ashby and Alfonso-Reese (1995) discussed the problem that organisms often encounter exemplars one at a time spread out in time. But then how is the organism to estimate the underlying statistical distribution of these exemplars? Their idea was that if prototype-based categories were encountered very frequently in nature, the organism could safely come to expect that structure, producing a distinctive processing advantage as that structure organized the next exemplar pool. These authors speculated that animals may actually be tuned this way cognitively, because the world may be tuned this way. Conversely, though, if nature continually presented chaotic exemplar distributions, the organism would have to drop all prior assumptions, and then an exemplar-memorization approach would become uniquely powerful.

Smith (2014) situated the results in section “[Prototypes and Exemplars in Animal Categorization Research](#)” ecologically. If monkeys constantly faced chaotic category structures requiring exemplar memorization (e.g., XOR

tasks), then they would not have survived, or else they would have developed a robust exemplar capacity. That they have not developed that capacity suggests that the world is not exemplar demanding in that way. But if the world were mostly averageable into prototypes and family-resemblance clusters, then prototype processes might have proved advantageous – as suggested by Briscoe and Feldman (2011) and Ashby and Alfonso-Reese (1995) – and selected for during cognitive evolution. Then, monkeys would resonate strongly to prototypes as shown here. They would make a default family-resemblance assumption as they do. They could safely be lousy at exemplar memorization, as they are. In short, monkeys’ categorization could be a good illustration of Shepard’s (2001) idea that cognitive systems are sometimes shaped by the structure of the natural world.

In fact, it does appear that nature rarely presents chaotic categories demanding exemplar processing. Rather, monkeys experience things such as snakes, leopards, eagles, insects, nuts, seeds, and so forth – all coherent family-resemblance categories, all prototype averageable. Malt (1995), in a seminal review, drew on cognitive and cross-cultural studies to describe the generic category structure that characterizes natural kinds and is accorded psychological preeminence in all human cultures worldwide.

All in all, there is a consensus that there are probably multiple processes potentially underlying category learning, with organisms potentially tuning toward different processes for different niches, tasks, and situations. However, the animal research suggests an imbalance among these processes given an evolutionary tuning between prototypes in mind and family-resemblance categories in nature. In essence, animals have sent the message through their results that they have not relied on exemplar processes in category learning for a hundred million years. In this, they have made an extraordinary contribution to categorization science, even refocusing the human literature. This area shows the constructive synergies that are possible across human and animal research.

## The Search for Rules and Hypotheses in Animal Categorization Research

The search for animals' rules/hypotheses during category learning has deep roots in comparative psychology. Noncontinuity theory proposed that animals spontaneously tune their receptors toward one focal dimension in discrimination learning (an attentional "hypothesis"). Classical Theory tried to define categories by criterial features best learned as rules (bachelor: unmarried). Krechevsky (1932) reported on uncertain evidence that even rats were trying out dimensional hypotheses during discrimination learning. Harlow's (1949) work on animals' learning-set rules (that allowed instantaneous behavioral reversals) is well known. His lingering doubt is less well known: He wondered whether the labels "rule" and "hypothesis" should be given to learning sets that are wordless/languageless. Still today, language and verbalization are important theoretical considerations in this area. This area has been strengthened by its integration with cognitive neuroscience. In fact, neuroscience provides a good introduction to this area, through its careful differentiation between explicit and implicit systems for category learning.

*Dissociable category-learning systems.* One candidate learning system – the explicit system – is allied to the cognitive utilities of executive attention and working-memory that could support hypothesis testing and rule learning. This system would generally map onto brain circuits involving prefrontal cortex, the anterior cingulate gyrus, the hippocampus, and so forth. This system displays typical features. It learns low-dimensional category rules through active hypothesis testing, possibly discovering rules suddenly through conscious insight. These rules are accessible to declarative cognition (verbalizable by humans).

Another system – an implicit system – is allied to operant learning and the brain's reinforcement mechanisms. It is likely grounded in the basal ganglia – the caudate nucleus is well situated to associate percepts through to responses. Learning in this system (e.g., discrimination learning)

occurs associatively through processes akin to conditioning – slowly and gradually, with category "knowledge" not present in working memory, not conscious, and not verbalizable or otherwise declarable.

Readers will see immediately how this dissociation from neuroscience is relevant to comparative research. Were the attentional foci of noncontinuity theory protorules? Were Krechevsky's rat "hypotheses" akin to human hypotheses? Did Harlow's learning sets amount to explicit performance rules? One can fairly ask whether other species than humans share something like this dissociative structure of implicit/explicit category learning, and especially whether they share something like an explicit learning system more toward the conscious/declarative pole of cognition. But to do so, one must come armed with appropriate dissociative paradigms.

Figure 6 shows a useful paradigm. Its categories (the stimulus ellipses) are defined within a two-dimensional perceptual space. For example, stimuli might be boxes defined over 100 sizes and 100 densities of internal lit screen pixels. In the figure, each black (Category A) or gray (Category B) symbol would specify the bidimensional dimensional specification and perceptual appearance of a particular exemplar. Participants of course would never be shown this map of the category structure but would have to learn to differentiate the categories based only on trial-by-trial cycles of stimulus-response-reinforcement. In such a task, one could insightfully realize conscious dimensional rules, or slowly develop conditioned, unconscious response habits. This paradigm lets one diagnose these different learning strategies.

The rule-based (RB) task (left panel) favors explicit rules. Dimension Y – only – contains valid category information. A dimension Y rule is optimal. It is known (e.g., Smith et al. 2014) that humans' rules in these tasks are explicit – held in working memory – conscious, narrowly dimensional, and declarative in language. The information-integration (II) task (right panel) defeats rule use, because both dimensions offer only partial category information. Instead, one must integrate information across dimensions

**Categorization, Fig. 6** Rule-based and information-integration category structures. *Note.* Left: A rule-based category structure depicted within an abstract  $100 \times 100$  stimulus space. The black and gray symbols, respectively,

indicate Category A and Category B stimuli. Right: an information-integration category structure, depicted in the same way

(hence the II descriptor). The cognitive system accomplishes this integration implicitly – essentially learning a low-level response habit that responds accurately without awareness.

The RB and II tasks are only a slight rotation apart in perceptual space. They are equal in category size, within-category exemplar similarity, between-category exemplar dissimilarity, structural ratio, and linear separability – those aspects of category structure discussed above. They are a minimal pair of category tasks that contrast only in the learning process they elicit from human minds. And so, they have utility for comparative researchers because they may allow researchers to assay implicit and explicit categorization in animal minds, too.

Accordingly, researchers gave humans and macaques RB and II tasks (reviewed in Smith et al. 2012). Humans (Fig. 7, left panel) strongly preferred rule tasks, learning these much faster to higher terminal-performance levels. (They also verbalized their unidimensional category rules.) Macaques (right panel) produced the identical RB advantage, though they learned more slowly (and said nothing!). The researchers suggested that macaques share with humans some – not all – aspects of the hypothesis/rule system that humans access through consciousness and language. There is generous room for further

research to specify both these unshared and shared aspects.

Zakrzewski et al. (2018) demonstrated an important unshared aspect. Following on research by Ashby and his colleagues, she showed that humans' rule knowledge is fully abstract and freely transferable to new stimulus domains that are different in perceptual appearance. She made this demonstration by training humans on RB and II tasks in one region of perceptual space, and then transferring them to a new region (Fig. 8). Humans transferred perfectly in the RB task (left panel), signifying that their category learning was abstract enough to be applied to novel stimuli. However, transfer faltered in the II task (right panel), signifying that their implicit category knowledge was welded to the original stimulus contexts of training (as would be expected for associative, stimulus-response learning).

However, Zakrzewski et al. (2018) found a different result with macaques. Even their performance-advantaged, supposed rule knowledge in the RB task faltered badly at transfer. That knowledge was poorly transferable, not abstract and general as human's rule knowledge is. It is an interesting riddle to explain why macaques show such strong performance advantages on RB tasks over II tasks, while still

**Categorization, Fig. 7** Humans’ and macaques’ performance in rule-based and information-integration Tasks. *Note.* Left: Proportion of correct responses in each 10-trial block for 30 humans who performed 600 trials of a rule-based (RB) category task (open symbols) and an information-integration (II) category task (filled symbols). Right: proportion of correct responses in each 100-trial block for three macaques who performed 6,000 trials of

an RB and II category task, depicted in the same way. (From “Implicit and Explicit Categorization: A Tale of Four Species” by J. D. Smith, M. E. Berg, R. G. Cook, J. Boomer, M. J. Crossley, M. S. Murphy, B. Spiering, M. J. Beran, B. A. Church, F. G. Ashby, & R. C. Grace, 2012, *Neuroscience and Biobehavioral Reviews*, 36, p. 2359–2360. Copyright 2012 by Elsevier. Reprinted with permission)

**Categorization, Fig. 8** Category structures to test the transferability of category knowledge. *Note.* Training trials were drawn from the long stimulus ellipses that extended across 80 stimulus levels. In transfer, 25% of trials presented stimuli from the short ellipses that extended across 40 stimulus levels. (From “The Transfer of Category

Knowledge by Macaques (*Macaca mulatta*) and Humans (*Homo sapiens*)” by A. C. Zakrzewski, B. A. Church, & J. D. Smith, *Journal of Comparative Psychology*, 132, p. 62. Copyright 2018 by the American Psychological Association. Reprinted with permission)

demonstrating – even in RB tasks – some stimulus-bound aspects typical of associative-learning processes.

*Alternative reinforcement environments.* Smith et al. (2018, 2020) demonstrated an aspect of explicit category learning shared between animals and humans. The brain's primary reinforcement mechanisms are time constrained. Thus, associative learning depends on the temporal contiguity among stimulus, response, and reward. This dependence has been appreciated since Pavlov. Yagishita et al. (2014) used an elegant technique to gain temporal control over stimulus and reward brain pathways. He showed that even a 2 s temporal separation made associative learning falter.

The method of temporally displacing reinforcement is thus a powerful tool by which comparative researchers may disable important forms of associative learning, so to study the alternative forms of learning that humans and animals turn to instead. For example, Smith et al. (2018) used trial-lagged reinforcement – after each trial, participants received feedback not on that trial but on the previous trial. In this way, the reinforcement signal was displaced away from the SR pairing, perhaps untrackably to an associative-learning system. But an explicit-declarative hypothesis-testing system could hold in working memory the hypothesis it was actively considering and judge how well that potential category rule was generally faring over trials. Predictably, then, Smith et al. (2018) found that displaced reinforcement impaired II learning, suggesting that necessary associative processes were disabled by that reinforcement regimen. But displaced reinforcement left RB learning intact, suggesting that RB tasks tap explicit-declarative cognitive processes that proceed independently of trial-by-trial reinforcement.

Smith et al. (2020) made an initial demonstration in this area with macaques. Macaques learned discrimination tasks well even given only trial-lagged feedback. This reinforcement regime does more than just delay the animal's receiving reinforcement – associative learning processes might bridge this delay interval in some way. It also reinforces a previous trial after a second stimulus has masked the first stimulus, and a second response has masked the first response. This

could make assigning reinforcement credit associatively very difficult. Macaques should fail to learn in this situation if they have no alternative system of learning on which to draw. They do not fail.

A strong contender for the alternative system of learning they are turning to is a kind of hypothesis-testing strategy, shown by humans in the identical paradigm, proposed for animals by Krechevsky (1932) nearly a century ago. Therefore, the method of displaced reinforcement may hold great promise. It is a transformative idea that one can dissociate away the important processes of associative learning by disabling them, leaving the animal to use – if it can – other learning processes that may lie on a more explicit-declarative level.

*A broader comparative perspective.* The theoretical import of this issue is sharpened by taking a wider species view. Researchers studied pigeons' RB-II performance (reviewed in Smith et al. 2012) but found qualitatively different results than with humans and macaques (Fig. 9). Now there was no RB performance advantage – pigeons learned RB and II tasks equally fast and to the same level. It seemed the pigeons were learning two tasks of the same difficulty and psychological character (to them!), without preferring or possibly even realizing the unidimensional rule embedded in one of them. This equivalence would be predicted if pigeons were processing the task stimuli holistically or integrally (not dimensionally and analytically). This equivalence could even suggest that pigeons lack the selective-attention capacity to bring the RB task's dimensional rule into sharp focus. Rats also appear to show “the pigeon result,” extending that pattern to another vertebrate lineage (Broschard et al. 2019). Thus, two species pillars of comparative cognition – rats and pigeons – show nonanalytic categorization without the dimensional analysis or rule preference shown by primates. The differences across vertebrates, primate species, and humans encourage the theoretical idea that animals' categorization capacities are potentially multifaceted and layered, rather than explainable as just a unitary associative-learning capacity or just a unitary exemplar-memorizing capacity.

**Categorization, Fig. 9** Pigeons learning information-integration (II) and rule-based (RB) tasks. *Note.* The proportion of correct responses by session is shown from the criterial block backward for 8 II-learning pigeons and 8 RB-learning pigeons. (From “Implicit and Explicit Categorization: A Tale of Four Species” by J. D. Smith, M. E. Berg, R. G. Cook, J. Boomer, M. J. Crossley, M. S. Murphy, B. Spiering, M. J. Beran, B. A. Church, F. G. Ashby, & R. C. Grace, 2012, *Neuroscience and Biobehavioral Reviews*, 36, p. 2364. Copyright 2012 by Elsevier. Reprinted with permission)

## The Search for Relational Concepts in Animal Categorization

Researchers have also studied animals' capacity to learn conceptual categories that are grounded in relations like sameness. Here, too, humans present the gold standard of relational cognition, for it grounds humans' higher-level cognition (e.g., analogical reasoning). Indeed, many have suggested relational cognition as the locus of a fundamental discontinuity between animal and human cognition.

A very early relational task shows that the theoretical stakes are high in this area. In a transposition task, a positive S+ stimulus (e.g., a Size 4 disk) is rewarded in training, in contrast to a nonrewarded S- (e.g., a larger Size 5 disk). Then, subjects are tested for their choice preference between Size 3 (a novel stimulus) and Size 4 (the rewarded S+ stimulus). Animals from

chimpanzees to chickens choose the smaller Size 3 disk, apparently acting against their associative learning. Behaviorists reacted strongly against results like this because they might show animals transcending their stimulus reactions in favor of relational cognition. Spence's (1937) Peak Shift model took direct aim at such results, though it could not explain all relevant findings (Gonzalez et al. 1954). (As a matter of history, the Gestalt psychologists loved the transposition results because they showed animals processing whole perceptual Gestalt configurations.) The study of relational cognition has always placed the behaviorist and cognitivist theoretical approaches in opposition.

*Pigeons: A fragile same-different capacity.* Recently, the same-different task has been dominant, with animals needing to identify a relation of sameness or difference. The matching-to-sample task could be one such task. A stimulus is presented (the sample), and later the animal must select the sample again when it is presented along with the foil. However, this successive task (with the sample presented at two points in time) is problematic, because animals might respond successfully by just gravitating behaviorally toward a “hot” or fluent trace in immediate memory, rather than responding toward the abstract relation of same.

Nonetheless, the matching task has played a valuable role. Zentall and his colleagues (e.g., Zentall and Hogan 1974) trained pigeons on matching tasks in one stimulus domain and then transferred them to another. They could confirm that they have learned an abstract relational rule – respond same – by transferring that rule to the new stimulus domain, but they did not do so. This suggests that pigeons are using some low-level stimulus cue that is domain specific, not the true relational strategy.

Most researchers now accept that the simultaneous same-different paradigm is the more robust way to test animals' capacity for relational cognition. Here, the animal sees two stimuli simultaneously and chooses between its same and different abstract response icons (e.g., the letters S and D). This task cannot be solved by memory fluency, because no sample is presented twice, and

because the response icons bear no resemblance to the trial's stimuli. Still, pigeons have great difficulty identifying pairs of stimuli that are same or different.

Seeking to create stronger relational displays for pigeons, researchers have used 16-item simultaneous same and different displays (e.g., Young et al. 1997). Now pigeons can reliably discriminate same arrays from different arrays. However, this task presents an interpretative difficulty, because it contains a low-level perceptual (visual-entropy) cue. The 16-item same displays appear visually calm and regular; the 16-item different displays appear visually noisy. This first-order visual cue is directly perceivable and requires no abstract relational judgment. Thus, once again, pigeons are not showing a robust relational capacity in this task. In fact, as the visual arrays shrink from 16 items to 8 items to 4 to 2, pigeons' performance collapses, demonstrating that the entropy cue is dominant. Humans' performance does not collapse.

Of the well-tested species, pigeons have the most limited same-different competence. Premack (1978) concluded that it would be difficult to "talk to a pigeon" because they respond so strongly to absolute stimulus cues and so weakly to relational cues. If you tried to shop with a pigeon, you would constantly think "this will go great with my couch" – a relational thought. The pigeon would think "it's teal; it's definitely teal" – an absolute-stimulus perception). The pigeon same-different research is a major achievement of modern research in animal categorization, because it characterizes so clearly the capacity of an important research species in an important comparative area.

*The transitional same-different capacity of primates.* The difficulty of simultaneous same-different tasks is that the animal must transcend the first-order perceptual appearance of the test stimuli. Two identical stimuli may be same whether they are grapes or Cheerios. This is why relational responding is deemed cognitively sophisticated and why it may be phylogenetically restricted as we have just seen.

Even the nonhuman primates find relational tasks difficult and taxing, so that they default

instead to first-order, stimulus-based strategies. Illustrating this default tendency, Shields et al. (1997) tested macaques with pairs of stimulus boxes filled with lit pixels. The box pairs could be (1) sparse and same density, (2) sparse but different density, (3) dense and same density, or (4) dense but different density. Animals were to make the response same for box-pair type 1 and type 3, and the response different for box-pair type 2 and type 4. But instead, macaques strongly gravitated toward contrasting box-pair types 1 and 2 from box-pair types 3 and 4 – a first-order sparse-dense perceptual strategy instead.

Premack (1978) provided a thought-provoking rule of thumb to this area. He suggested that probably many vertebrate species process both absolute stimuli and abstract relations as they perceive and conceive their worlds. But the question is the balance between these processing channels. One could say that for pigeons the absolute stimulus channel is loud but the abstract-relational channel soft, creating their performance tendencies in same-different tasks. One could say that for monkeys the two channels are almost at parity, so that macaques default to absolute stimuli but can transition to abstract relations. Several lines of research show that macaques and monkeys have more robust same-different capacities than do pigeons. Premack's further thought on the basis of this rule was that apes should join humans in thriving in relational-cognition task, and this is probably true as well.

*Higher-order relational performances by primates.* In fact, there are higher-level relational tasks for testing (possibly) higher-level species. The preferred task for this purpose is the relational matching to sample task (RMTS). In this task – illustrating here with a same trial – the animal would see as a sample two identical photos of pizza slices. Later, another pair of identical photos (say, two identical keys) would be given as one (the correct!) matching choice, and a pair of different stimuli (say, a banana and a yo-yo) would be given as the other (incorrect!) matching choice. Now, to make the relational choice, one really must let go the concrete perceptual appearance of things, reflecting on abstract relationships only.

In research by Thompson and his colleagues, several chimpanzees (*Pan troglodytes*) succeeded in an RMTS task, as did chimpanzee Sarah in David Premack's research. Based on results like these, Thompson and Oden (2000) famously made a theoretical distinction between the paleological monkey (concretely perceiving, not succeeding on RMTS trials) and the analogical ape (abstractly conceiving, succeeding on RMTS trials and perhaps on other analogical-reasoning tasks). These results did extend Premack's intuitive rule of thumb farther through the primate species. Perhaps the relational channel is gaining additional psychological volume.

However, these ape studies did have an unavoidable confound. The participant chimpanzees had extensive laboratory-training histories, in which they were all given forms of abstract symbol training, and in one case even abstract tokens denoting the relations same and different. This relational symbol training alone could have fostered relational cognition, besides the cognitive sophistication of inherent chimpanzeeness.

Nor do humans escape this confound. Declarative language provides a vast symbolic resource to us. Formal schooling teaches relational cognition relentlessly. It is good to remember that just as chimpanzees reflect their training history in their cognitive successes, so do we, and not all those successes purely reflect our inherent humanness.

Monkey species perform differently in RMTS tasks from ape species. For example, Smith et al. (2013) used a perceptual fostering paradigm to facilitate macaques' RMTS performance. A training RMTS task gave macaques a first-order perceptual cue and a second-order conceptual cue on each trial. Just as was discussed above, macaques defaulted to using this perceptual cue. But then the first-order perceptual cue was gradually weakened, using the random-polygon method described in section "[Prototypes and Exemplars in Animal Categorization Research](#)" here. The hope was to wean macaques from their perceptual default, leaving them to match relationally. That hope was dashed. As the perceptual cue was weakened, macaques' performance disintegrated at a quantifiable faintness of the perceptual cue. There was an intriguing perceptual-conceptual

barrier that the macaques could not cross psychologically. Their relational capacities are restricted.

Fagot and Parron (2010) used a spatial fostering paradigm with baboons (*Papio papio*). Their RMTS task began with conjoined color patches as sample and choice stimuli, so baboons were essentially matching long color bars to one another. Later, the bars were divided to be separated spatially, so that baboons had the chance to match conceptually pairs of same or different color bars. This progressive training also failed. Baboons' performance faltered given even a small spatial gap. Fagot and Parron (2010) concluded the baboons did not group the spatially separated elements into a higher order relational structure.

Flemming et al. (2011) tried to contrast their same and different RMTS trial by giving these two trial-kinds different outcomes (e.g., correct same and different responses might earn double or single food pellets, respectively; incorrect same and different responses might earn long or short time-outs). This hedonic fostering approach also failed. Macaques seemed to show some relational matching during differential outcome training but dropped to chance when differential outcomes were removed.

Monkey species do not universally fail RMTS tasks. Fagot and Thompson (2011) trained baboons doggedly in RMTS tasks. Of 29 baboons tested, 6 achieved 80% correct given 15,000–30,000 trials on an RMTS task constructed using ten repeating geometric shapes. Five baboons showed some retention of their successful RMTS performance over a year. Thus baboons (and very possibly their close phylogenetic kin macaques) have some cognitive capacity for conceiving and matching relational sameness and difference.

All in all, the nonape findings document the empirical shyness of RMTS performance absent supplementary supports (spatially contiguous stimuli, differential outcomes, and perceptual similarity). However, they do not document the absence of that capacity, given the findings of Fagot and Thompson. In fact, these results reinforce Premack's intuition that the nonape primates represent transitional species, strongly attracted toward low-level perceptual cues, but still having some potential for responding relationally,

enough to show glimmers of RMTS success. To us, these results suggest that the monkey species are ideal for studying the roots of humans' sophisticated relational matching and analogical reasoning capacities. Here, too, as with the literature on category rules already discussed, it seems best to consider that a two-level or two-layer conceptualization of categorization may be best for organizing the empirical findings theoretically. A unitary-process description emphasizing animals' associative learning does not seem to do so as effectively. And modern neuroscience perspectives may usefully formalize Premack's intriguing rule of thumb, with multiple systems of learning standing in for multiple volume controls in mind.

## A Broader Synthesis

This multiple-systems perspective appears to offer new ways to understand a broad range of findings in comparative psychology. Two important areas of animal categorization research – those discussed in sections “[The Search for Rules and Hypotheses in Animal Categorization Research](#)” and “[The Search for Relational Concepts in Animal Categorization](#)” – draw a similar phylogenetic map of different cognitive capacities. Section “[The Search for Rules and Hypotheses in Animal Categorization Research](#)” showed that humans and other primate species show strong performance advantages on rule-based tasks and share the ability to still learn rule-based category tasks when trial-by-trial reinforcement is absent. These results show human-primate continuities in aspects of the explicit-declarative category-learning system that rule tasks emphatically elicit in humans. In contrast, several converging studies show that pigeons appear not to favor rule-based category tasks at all. These findings are distinctive because one might suppose that single-dimensional category differentiations would obviously be psychologically simpler and preferred. They are not. Rats have also failed to process rule tasks with psychological privilege. Thus, not all species have made the preliminary steps toward rule-based categorization that primates have made and that humans have robustly

made. Given all of these findings, a possible hypothesis is that rats and pigeons illuminate a stem, ancestral vertebrate category system that clearly functions beautifully in managing the perceptual, family-resemblance category tasks discussed in sections “[Prototypes and Exemplars in Animal Categorization Research](#)” and “[What Kinds Are Natural?](#)” here. There is broad species continuity in this domain. However, it seems that some species supplement these basic categorization processes with others that emphasize stimulus analysis, dimensional attention, and possibly primitive forms of hypothesis testing. This shared dimensional-attentional cognitive ground will be important to study in future comparative research.

Section “[The Search for Relational Concepts in Animal Categorization](#)” drew the same species map – but now regarding the relational-judgment tasks. Smith et al. (2013) showed that humans discover their relational rules in sudden, conscious insights, just as they do category rules. Smith et al. (2019) showed that working-memory interference impairs humans' relational learning and RMTS performance. These results suggest that humans' relational performance – just as their rule-based category learning – falls more toward the explicit-declarative pole of cognition.

Monkeys learn same-different tasks robustly, and some data even suggest some explicit cognitive processes attending this learning. For one thing, monkeys can make metacognitive uncertainty judgments regarding their same-different performance (Shields et al. 1997). For another thing, baboons' RMTS performance is impaired – just as it is in humans – when a concurrent cognitive load is present (Maugard et al. 2013). However, in this domain, too, monkeys were shown to have clear constraints in performance facing higher-level relational tasks. And here, too, pigeons in multiple studies have shown a minimal capacity for performing relational tasks, unless provided directly perceivable cues like the visual calm or busyness of multiple-item same and different displays. Again, a natural hypothesis is that some species are supplementing the basic perceptual-level processes of many vertebrate species, with this supplementation more clearly displayed by the primates.

This pattern even transcends the domain of categorization. In the large literature on animal metacognition (entry ► “Meta-Cognition” in this volume), consensus holds that animals’ metacognitive performances cannot be explained through a unitary system of associative responding but requires assuming more executive cognitive processes monitoring associative processes. For example, research shows that a working-memory load suppresses macaques’ metacognitive reports while leaving intact their primary perceptual responses within a task. Humans show this effect, too. The same concurrent-load phenomenon is observed in baboons and humans’ RMTS performance, and in humans’ rule-based category learning.

However, pigeons have consistently not demonstrated clear forms of uncertainty responding or metacognition, just as they have not shown robust relational learning or advantaged rule-based category learning.

Thus, a major contribution of animal categorization research is to point out this broad convergence. Many findings – on rule-based categories, relational cognition, and even metacognition in rats, pigeons, monkeys, baboons, apes, and humans – recommend a new theoretical perspective, one that envisions a basal vertebrate system of associative learning and perceptual categorization that in some species is supplemented with some kind of more decisional and working-memory-intensive processes. Really, one must give Premack full credit for his important working analogy in this area, with absolute-stimulus control softening through cognitive evolution, but relational appreciation strengthening. We would just add to that view that the basic stimulus-associative system is being layered over with a system more similar to humans’ explicit-declarative system of cognition and categorization. This addition will not be surprising to students of human cognition. They will know that the same overlaying of implicit processes by explicit processes is the hallmark of contemporary cognitive science that has revolutionized cognitive theory. Thus, animal categorization research foreshadows the potential transformative influences that a similar systems approach could have within comparative psychology.

## Synonyms

Day-night activity; Diel activity; Polyphasic activity pattern

## Definition

Translated as “through the day” in Greek, this behavioral trait is a non-adherence to a strict

diurnal (i.e., active during the day) or nocturnal (i.e., active during the night) activity, often showing several peaks over the diel (i.e., 24 h cycle) day (Tattersall 1987).

## Introduction

Cathemerality is a term applied to the pattern of an organism's activity that occurs during both the light and dark portions of the 24 h cycle. Thus, a cathemeral organism does not strictly adhere to a diurnal (i.e., active during the day), nocturnal (i.e., active during the night), or crepuscular (i.e., active during twilights) phase, but rather shifts its activity throughout the 24 h. Put more simply, “the activity of an organism can be regarded as cathemeral when it is distributed approximately evenly throughout the 24-h of the daily cycle, or when significant amounts of activity, particularly feeding and/or travelling, occur within both the light and dark portions of that cycle” (Tattersall 1987). The word “significant” assumes a particular importance in Tattersall's definition. In fact, it is important to note that bouts of activity that include only a few behaviors (e.g., vigilance or body movements within a sleeping tree) or that account only for a small proportion of the overall activity during the 24-h cycle (the threshold is usually set at 10%) should not be enough evidence to consider a species cathemeral. Several activity patterns (i.e., monophasic, biphasic, or polyphasic) or activity rhythms (i.e., circadian or ultradian) may result in cathemeral activity (Halle and Stenseth 2000).

Sometimes it is difficult to classify a species' activity as cathemeral as this is an intrinsic flexibility that may not be evident when ecological conditions do not make this behavior advantageous. The description is especially problematic when species activity is described in captivity or over one season or in a limited number of localities as the animals react to local conditions that may make them fully diurnal or fully nocturnal, thus masking this behavior (Fox and Bellwood 2011; Donati et al. 2013).

Light and dark phases of the diel (i.e., 24-h cycle) day represent contrasting sensorial environments (Halle and Stenseth 2000; Donati

and Borgognini-Tarli 2006). As opposed to a year-round diurnal or nocturnal activity, or even crepuscular activity, taxa exhibiting cathemerality are presented with the challenge of compromising between adaptations for light and dark phases of the 24-h cycle (Prugh and Golden 2014). Even if the visual characteristics of cathemeral animals are often mixed between diurnal and nocturnal traits, they appear to exhibit an intermediate visual morphology allowing them to cope with these contrasting demands (Donati and Borgognini-Tarli 2006).

Cathemerality is inherently flexible and is exhibited across a wide array of organisms, including temperate and tropical fish (Fox and Bellwood 2011), reptiles (Vermunt et al. 2014), and many mammalian Orders within Metatheria, Prototheria, and Eutheria (Curtis and Rasmussen 2006). As cathemeral taxa inhabit a diverse range of ecoregions (e.g., arctic, temperate, and tropical), the environmental pressures within each are highly variable. Thus, cathemeral activity may confer different adaptive advantages within each habitat (Curtis and Rasmussen 2006; Fox and Bellwood 2011). While cathemeral activity appears common among mammals, it is very rare in primates and thus has become the focus of intense research (Donati et al. 2013). Some primates in the Cebidae family (i.e., *Aotus* spp.) and the Lemuridae family (i.e., *Eulemur* spp., *Haplemur* spp., and *Lemur catta*) regularly display cathemeral activity patterns in a variety of habitats (Donati and Borgognini-Tarli 2006; Donati et al. 2013; Eppley et al. 2015).

## Environmental Cues

For cathemeral taxa, activity cycles are modulated by external factors (e.g., lunar luminosity, temperature) that either stimulate or inhibit activity at certain times of the 24-h day (Donati et al. 2013; Eppley et al. 2015; Halle and Stenseth 2000). Variations in day-length due to the seasonal shift of sunrise and sunset times can act as a zeitgeber, that is, an environmental cue that works as a synchronizing or an entrainment agent to control the onset and cessation of activity. Because of this

tight link with photoperiodic variations, temporal activity shifts are often associated with seasonal changes in light-dark ratios that provide a somewhat reliable cue when describing cathemerality (Donati et al. 2013). This also implies that at higher latitudes, the duration and distribution of activity change dramatically due to significant seasonal changes in daylength (Halle and Stenseth 2000). Among many mammals, moonlight suppressed nocturnal activity (Prugh and Golden 2014), though for most cathemeral primates, lunar luminosity increases nocturnal activity (Donati et al. 2013; Eppley et al. 2015). Regulated by photoperiodic changes and nocturnal luminosity levels, these daily activity variations are undoubtedly linked with the degree of habitat seasonality of the taxa studied.

## Adaptive Value of a Flexible Activity Pattern

Across various taxa, cathemeral activity has been linked to a multitude of non-mutually exclusive explanations, including thermoregulatory strategies to avoid cold/heat stress, anti-predator strategies, metabolic dietary-related needs, and the avoidance of interspecific competition (Curtis and Rasmussen 2006; Donati and Borgognini-Tarli 2006).

Thermoregulatory strategies, i.e., the avoidance of extreme temperatures, appear to be a common driver for cathemeral activity across many taxa. For example, some large herbivores such as eastern grey kangaroos (*Macropus giganteus*) reduce heat stress during the hot daylight hours by resting in the shade, and as a result, they increase nocturnal activity (Clarke et al. 1995). Some small- and medium-sized mammals have been recorded to constrain their nocturnal activity during days of low ambient temperature (Halle and Stenseth 2000), a thermoregulatory strategy also employed by tuatara (*Sphenodon punctatus*) (Vermunt et al. 2014).

Foraging success is determined by the need to minimize predation risk, thus activity patterns influence the probability of interactions among predators and prey. For example, in several brown lemur species (*Eulemur* sp.), a shift towards

nocturnal activity can reduce the perceived risk from diurnal predators, representing a predator avoidance strategy (Curtis and Rasmussen 2006). Predation masking effects have been observed in a tropical reef fish, the golden lined rabbitfish (*Siganus lineatus*), which completely shifts its activity pattern based on potential predation pressures in specific habitats (Fox and Bellwood 2011).

In many small mammals, cathemerality is a behavioral strategy to cope with seasonal dietary shifts and increase foraging efficiency. Basically, activity is extended across the full 24-h period in order to maximize energy and nutrient intake. This is a consequence of small body size causing an extremely high relative metabolic rate and a limited capacity for fiber digestion, as observed in shrews and voles (Halle and Stenseth 2000). In primates with simple digestive systems (e.g., *Eulemur* spp.), cathemerality may explain shifts in activity during periods of increased fiber intake (Donati et al. 2013).

Lastly, cathemerality has been suggested as a strategy to minimize interspecific competition. Among species that are morphologically and ecologically similar, a variation in activity cycle may assist in maintaining sympatry, i.e., existing in the same geographic area, when the expected potential for competition is strong. Several studies on mammals offer evidence of temporal niche partitioning by shifting their 24-h activity. For example, the short-tailed vole (*Microtus agrestis*) maintains activity during its preferred time window, while the sympatric bank vole (*Myodes glareolus*) shifts its activity peaks (Halle and Stenseth 2000). In the seasonal dry forests of north-western Madagascar, mongoose lemurs (*Eulemur mongoz*) and common brown lemurs (*Eulemur fulvus*) show different patterns of cathemerality to minimize the overlap in core home ranges, sleeping sites, and diet (Curtis and Rasmussen 2006).

## Conclusion

In conclusion, cathemeral activity provides varying adaptive values in different ecological contexts. This activity is clearly not the result of a single ultimate reason but rather the ability

to adjust behaviorally to different biotic and abiotic pressures. In all cases, the advantages of cathemerality must be significant since the lack of specialization toward one of the phases of the 24-h cycle comes with high costs for an animal, e.g., being exposed to diurnal and nocturnal predators or temperature extremes.

## Definition

Mental processing of environmental and social information and sensory input in salamanders.

## Introduction

There are approximately 8,000 species of known amphibians, about 500 of which are salamanders (Frost 2019). Amphibians arose about 360 million years ago with the oldest salamander fossil dating to the Miocene (Petranka 1998). Members of the class Amphibia are ectothermic tetrapods, lack scales, and have heavily glandular skin. Salamanders are unique from frogs and caecilians, most obviously, by always having a tail and forelimbs; a few salamander species lack hind limbs. Many species have biphasic life cycles where they spend the first portion of their lives in water and their adult life on land; however, there are some species that are solely terrestrial and solely aquatic (Petranka 1998). Modes of respiration include gills, lungs, and gas exchange through the skin (i.e., cutaneous gas exchange). Some groups and species (e.g., Proteidae, *Eurycea* spp.) are permanently aquatic, remaining in a somewhat larval form through life, and have conspicuous external gills. *Ambystoma tigrinum* heavily rely on gas exchange through lungs even as fully aquatic neonates. Adult *A. tigrinum* breathe through their nares or mouth using a two-stroke buccal pump (a method of ventilation where the animal moves the floor of its mouth in a rhythmic manner that forces air into the lungs). However, Plethodontidae lack lungs entirely and rely on cutaneous gas exchange.

Larval and adult-form (i.e., post-metamorphic) salamanders are carnivorous, with a diet consisting mostly of insects and other invertebrates. The largest species sometimes eat fish or small animals such as frogs and mice (Petranka 1998). Salamanders of the family Sirenidae (*Siren*, *Pseudobranchius*) also eat plant and algal material (Hill et al. 2015). Salamanders are prey to a variety of animals including fish, snakes, small mammals, birds, and invertebrates (Petranka 1998).

Cognitive research on all amphibians has been limited, especially compared to mammals and birds (Agrillo 2014; Kundey et al. 2016). Cognition is inarguably a broad field, so here we will mainly focus on how information from an

organism's environment may be used to modulate the organism's behavior. For example, quantitative discrimination is often used as a measure of cognitive ability, in contrast to nonnumerical discrimination (Agrillo 2014). Nonnumerical mechanisms that organisms may be using to discriminate quantities include the surface area of an object, density, amount of movement, element configuration, and/or overall brightness. For example, salamanders are able to discriminate between groups of live prey by choosing the larger group, but performance dropped to the chance level when the movement of prey was controlled for (Krusche et al. 2010). Concepts of cognition also extend to include mating behavior, recognition of individuals, territoriality, and foraging success, among others. By experimentally testing these behaviors in the lab and in the field, researchers are better equipped to infer which behaviors are instilled in organisms by instinct and what may be the result of learning from their environment.

## The Brain

Herrick (1948) provided a detailed description of the tiger salamander brain (*Ambystoma tigrinum*), which is an appropriate model for general brain structure of salamanders. The brain is divided into three main parts: the striato-amygdaloid complex, the hippocampus, and a large olfactory bulb. While brain function is not well studied in salamanders, the large olfactory bulb clearly is associated with the strong influence of pheromonal and other olfactory information on virtually all aspects of salamander natural histories. Apparently in anticipation of spring season foraging and mating, chemosensory cells and cells in the telencephalon portion of the brain, which contains the olfactory bulb, proliferate in number during this season (Dawley et al. 2000).

Roth (1987), with special attention to the visual system, also provided morphological descriptions of the brain. He also found that the visual perception and recognition of prey could be a useful tool for studying cognition, as he found that the

behavioral preferences of the salamanders for specific prey depended upon previous experience with those prey. He further generalized that movement by prey items is crucial to prey recognition in salamanders and coalesced these findings to posit a functional model of a neural "recognition module" concept.

## Cognitive Ecology

Cognitive ecology encompasses the interface of cognitive phenomena with the natural and social environments and experiences of an animal. Cognitive ecology is not itself a cognitive phenomenon, like memory may be. Rather, cognitive ecology is a framework to interpret the basic natural history and behavioral functions of an animal, from which we may infer some essential cognitive abilities. By considering the effects of information processing on animal fitness, the specifics of a species' cognitive ecology may be assessed. An example from feeding, which certainly is a direct influence upon fitness, prior to experience with prey appears to influence feeding behaviors. For example, naive *Plethodon cinereus* offered either dead or live fruit flies consumed more flies per minute on their second trial compared to their first, which is indicative of learning (David and Jaeger 1981). Additionally, adult *Plethodon cinereus* capture novel prey more quickly than do neonate or yearlings (Gibbons et al. 2003). Expanding beyond foraging behaviors, and more related to shelter and perhaps homing, salamanders (*Ambystoma tigrinum*) trained to either go left or right in a maze toward a reward of a moist microhabitat continued to go the direction in which they were trained even after the maze was rotated 180° (Kundey et al. 2016). This suggests that the salamanders preferentially used a learned turning response over visual cues.

## Courtship and Reproduction

Courtship is highly variable among salamanders, with few commonalities. In many species,

especially of ambystomatids, plethodontids, and salamandrids, courtship involves complex series of ritualized visual, physical, and pheromonal phenomena (Petranka 1998). For example, in some cases, the male deposits a spermatophore on the substrate and guides the female into the appropriate position so that she can take it up into the cloaca. In the best studied plethodontid salamanders, complex, coordinated, and species-specific courtship rituals include tail-straddle walks, physical contact, and body-stroking as part of the sequence to guide the female into position over the spermatophore. With no evidence to indicate learning, these displays and responses are assumed to be innate. Both males and females process spatial information, such as body size, for themselves and for potential mates during courtship displays. Such processing allows the salamanders to align the male's spermatophore with the female's cloaca. Roth (1987) reviewed experimental studies that demonstrated the importance of coloration in mate recognition and choice in aquatic newts (*Triturus* spp.) that have highly visual mating rituals.

### Quantitative and Numerical Discrimination

Organisms should evolve foraging strategies that maximize caloric gain while reducing caloric output. Functionally, such strategies would act as caloric intake/output calculators using information from numerosity and/or mass discrimination. This suggests that they should be able to distinguish a number of prey items and not just a larger overall quantity (i.e., mass) of prey. *Plethodon shermani* and *P. metcalfi* were given a choice of 8 versus 16 and 8 versus 12 prey items (crickets: *Gryllus bimaculatus*). They significantly chose 16 over 8, but there was no significant difference in the 8 versus 12 trials (Krusche et al. 2010). *Plethodon cinereus* chose the larger numerical quantity of prey (*Drosophila virilis*) when choosing between one versus two flies and between two versus three flies (Uller et al. 2003); but there were no differences when the animals were offered 4 versus 6 and 3 versus 4.

### Chemical Communication

All salamanders may rely heavily on olfactory cues in all aspects of their behaviors. Plethodontid salamanders have unique grooves in the skin of the snout that lead from the margin of the upper lip to the nostrils; the grooves encourage uptake of chemical cues from the substrate, or the body surface of other salamanders, directly into the nostrils and their sensory cells. Physical damage to these grooves, from external parasites or aggressive interactions with conspecifics, can reduce subsequent foraging abilities (Jaeger 1981). The importance of chemical sensation in salamanders is underscored by multiple examples of cave-dwelling species that are blind and swamp-dwelling species with very reduced eyes. Nevertheless, the eyes of salamanders are similar to those of all amphibians in having a unique visual sensory cell type known as green rods; these cells contribute to remarkable visual abilities in very low-light situations.

Salamanders may communicate sex and species identity information through pheromones. Jaeger and Gergits (1979) found that males and females of *P. cinereus* and *P. shenandoah* can discriminate between their own substrate versus a substrate upon which a conspecific had been housed. In addition, both males and females of *P. cinereus* avoided the substrates of conspecifics. However, female *P. cinereus* did not avoid substrates of heterospecific, male *P. shenandoah*. This suggests that salamanders exhibit pheromonal (conspecific) and allomonal (heterospecific) communication, and these chemicals may confer information about the species and sex of individuals.

### Visual Communication

While olfactory cues appear to be a primary source of perception in salamanders, Roth (1987) presented experimental and theoretical evidence supporting the importance of visual stimuli in salamanders, both in the context of feeding and mate selection. *Plethodon cinereus*, presented with dead prey items, used chemical

cues but not visual cues were used to successfully locate, recognize, and ingest prey (David and Jaeger 1981). In the wild, immobile prey may comprise 5% of the diet of these salamanders, indicating foraging is mediated both chemically and visually (Roth 1987). Immobile preys typically are not dead individuals, but rather items such as chrysalises or nonmoving snails, etc.

Fecal inspection is commonly observed in *P. cinereus*. Females that had been fed low-quality diets showed similar rates of squashing and inspection of fecal pellets of females and males that were fed a high-quality diet (Karuzas et al. 2004). The authors concluded that this behavior is used to select foraging areas. Males may take advantage of this behavior by defecating around their territory to attract females.

Larval and fully aquatic adult salamanders (e.g., *Amphiuma* spp.) have pressure-sensitive lateral line organs, as seen in fish and larval or fully aquatic frogs. The role of this sensory system in salamander perception has not been well studied.

## Homing, Migration, and Orientation

Sensory systems involved in orientation appear to include olfaction, magnetoreception, and extra-ocular (i.e., pineal) photoreception. Many species of salamanders spend much of their adult life in terrestrial habitats, migrating to appropriate bodies of water to reproduce. Semlitsch (2008, p. 260) defined amphibian migration as movements toward and away from aquatic breeding sites. This definition distinguishes the behavior from various forms of simple dispersal. Although migrating salamanders tend to remain in or return to the area of hatching, dispersal by populations into areas does occur (Semlitsch 2008), even if the associated exploratory excursions rarely are observed.

Long-distance homing behaviors, which differ from strict migrations, have been well studied in the newt *Taricha rivularis* (Twitty et al. 1964) and less so in a few other salamanders. When *T. rivularis* were displaced, their movements

were strongly oriented toward their home even when it was several kilometers distant from the release site. Such a displacement distance is far greater than would be typical of a breeding migration or individual dispersal.

## Territoriality and Nesting

Jaeger and Forester (1983) reviewed various forms of territoriality and agonism in plethodontid salamanders – the best studied group by far – but other groups also have been surveyed (e.g., ambystomatids; Ducey 1989). Four characteristics of territoriality in salamanders are as follows: (1) the individual must have a “space” to be defended; (2) the individual must have the ability to defend this space through agonistic behavior; (3) individuals demarcate the space through pheromonal or visual displays; and (4) individuals are able to resist intrusion from invading salamanders.

Familiarity with a territory affects a resident salamander’s aggressiveness with intruders (Nunes and Jaeger 1989). Other factors that influence territoriality include body size of the resident, body size of the intruder, reproductive condition (i.e., courting season), number of intruders, condition of the tail of either salamander (e.g., complete vs. incomplete, amount of fat reserves), and food quantity/quality in the territory. Residents of a territory are more likely to initiate aggression than the unfamiliar salamander introduced to the territory (Jaeger 1981). In addition, there was more aggression observed when a resident was in contact with an unfamiliar salamander compared to a familiar salamander. When aggressive, the salamander’s bite is directed toward the tail or snout. Salamanders keep important fat reserves in their tail, and scar tissue on the snout negatively affects a salamander’s chemoreceptive abilities, leading to decreases in individual fitness.

Anthony et al. (1997) compared aggressive behavior in intra- and interspecific contexts in two species of sympatric salamanders: *Plethodon ouachitae* and *P. albagula*. These species have similar ecological requirements, but *P. ouachitae*

is slightly smaller than *P. albagula*. *Plethodon ouachitae* were extremely territorial in both intra- and interspecific experiments, delivering bites 14 times more than in any previously studied *Plethodon* sp. Similar levels of aggression by *P. ouachitae* were observed when the salamander was an intruder into conspecific or heterospecific territories, indicating that elevated levels of aggression in this species also occur outside of the context of territorial defense.

The energy that male salamanders will expend defending their territory is proportional to the value of the territory. Adult male red-backed salamanders that have preferable prey (termites) are more likely to bite intruders than resident males that had less preferable prey (ants; Gabor and Jaeger 1995). Aggressively defending a territory sends honest signals to intruders that a territory is valuable. However, residents weigh these costs against the benefits of deterring the intruders. Female *P. cinereus* stay with their eggs while only occasionally leaving to forage, and her neonates stay with her for 2 weeks. Nest guarding behavior is known in many plethodontid species, as well as in Amphiumidae, Cryptobranchidae, and other examples. Kin recognition is consistent with the phenomena of territoriality and nest guarding and appears to occur in *P. cinereus*. Hungry females preferentially consume unrelated neonates compared to related neonates (Gibbons et al. 2003). Putative kin recognition and mother–offspring interactions have not been well studied beyond *P. cinereus*.

### Sexual Differences in Territoriality

Salamanders show sex differences in choice of cover, searching unoccupied territories, and in mate guarding behaviors. Mathis (1990) showed that choices of cover objects, for both males and females, are positively correlated with body size. After removing salamanders from a section of the forest floor, females invaded unoccupied territories more often than did the males. Females may be more competitive because not only does she have to brood her eggs there, but she also must

have sufficient prey (energy) in order to adequately provision eggs with yolk.

Males in a mated pair spend significantly more time threatening male intruders than do the females in the same mated pair (Lang and Jaeger 2000). However, when the intruding salamander is female, the female in the mated pair acts more aggressive than their male counterpart. Pairs co-defend territories, but not cooperatively because they show disproportional aggression toward same-sex intruders. In addition, both males and females aggressively attack their partners if the partner is anointed with pheromones from other opposite-sex individuals, which would indicate that they have been involved in social polyamory (Prosen et al. 2004).

There also are sexual differences in cost-benefit considerations of energy. For females, the cost-benefit ratio of territory defense depends on the number and sex of intruders, as Kohn et al. (2005) found that female salamanders defended their territory when one male was present, but not when there were two males present. In this case, it appears that the energy cost of defense was acceptable in the context of one male but unacceptable in the context of two.

Evidence suggests that females prefer substrates of partner males over those of unfamiliar males (Gillette et al. 2000). Social monogamy is preferential to both males and females because the female can take advantage of the male's resources and the male can insure that she will mate with him. However, males showed no preference between their partner's pheromones and an unpaired female. This suggests that adults display social polygamy when there is an unpaired female available. Additionally, interactions that display social monogamy are exclusively seen during the courtship season (Gillette 2003).

### Dear Enemy Recognition and Mating Systems

Dear enemy recognition (Jaeger 1981) is a phenomenon in which salamanders have territories in

close proximity to one another, where there will likely be an aggressive interaction between the residents. Regardless of the outcome, a second aggressive encounter between residents is less likely – evidently because the salamanders recognize their former enemies. *Plethodon cinereus* is able to distinguish between familiar and unfamiliar conspecifics. McGavin (1978) found that if a resident salamander was presented with either an unfamiliar salamander or familiar salamander, the resident bites the unfamiliar individual significantly more frequently. Similar results were found despite the sex of the resident.

Jaeger et al. (1995) found that juvenile *P. cinereus* are attracted to territorial pheromones of male and female adult *P. cinereus*. Adults were more tolerant of sharing their territory with a juvenile than an adult and more tolerant of a familiar juvenile compared to an unfamiliar juvenile.

## Conclusion

Much remains unknown about Caudata, but recent research suggests that salamanders are more cognitively complex than previously thought. There is evidence of intricate inter- and intraspecific dynamics both in the field and the lab. Clearly, cognitive abilities are manifest in many areas of an organism's life including searching for a territory, choosing a mate, and foraging, among others. Being the most basal group in the phylogeny of tetrapods, amphibians form the comparative basis for all other cognitive studies with tetrapods, as well as with fishes.

## Definition

Movement used by salamanders to traverse their environment.

The Caudata are amphibians that generally show the basal tetrapod body plan. They are lizard-like in appearance with slender bodies and short limbs (Girling 2013). They tend to have four toes on the forelimb and five on the hindlimb. Some fully aquatic species, like sirens and amphiumas, have reduced or absent hindlimbs. Like all amphibians, the Caudata have a distinct larval and adult stage. They have permeable skin that usually makes them reliant on habitats in or near water or other cool, damp places. Some salamander species are fully aquatic throughout their lives, while others take to the water intermittently, and others are entirely

terrestrial as adults (Duellman and Trueb 1994; Stebbins and Cohen 1997).

## Major Locomotor Modes

**Caudata locomotion** can be broken down broadly into terrestrial and aquatic movement (Duellman and Trueb 1994; Karakasiliotis et al. 2016; Stebbins and Cohen 1997) (Fig. 1). Terrestrial gaits in the Caudata are highly variable and characterized by considerable variation in both limb-loading (Granatosky et al. 2020) and timing (Ross et al. 2013). All terrestrial **Caudata locomotion** involve symmetrical lateral-sequence walking gaits in which each hindlimb footfall is followed by an ipsilateral forelimb footfall (i.e., right hindlimb, right forelimb, left hindlimb, left forelimb) (Fig. 2). Commonly, during walking gaits the forelimbs and hindlimbs are traveling together as a slightly asynchronous couplet. When the contralateral forelimbs and hindlimbs are traveling together, this is referred to as a diagonal couplet. Very rarely do the limbs move together in perfect synchrony (Cartmill et al. 2002;

Granatosky 2018). All the Caudata use a lateral-sequence diagonal-couplet footfall patterns (Karakasiliotis et al. 2016; Nyakatura et al. 2019; Reilly et al. 2006). This footfall sequence is inherently quite stable due to the generally low proportion of the stride spent as a unilateral bipod (~22%), and the relatively high proportion spent as a diagonal bipod (only two contralateral limbs in contact with the support) and large tripod (three widely splayed limbs in contact with the support).

Literature on gait transitions (a speed related switch from walking to running) in Caudata is scant and it does not appear that the Caudata can adopt asymmetrical running gaits (e.g., gallop or bound). Experiments on tiger salamanders reveal that gait transitions are not visually detectable based on limb phase definitions (Reilly et al. 2006). It is the case though that if one bases the definition of a gait transition off of center of mass movements rather than limb phase definitions then both walking and running center of mass movements are present (Reilly et al. 2006). However, the use of these walking and running center of mass movements are not speed dependent (Reilly et al. 2006) and therefore are not

**Caudata Locomotion, Fig. 1** The Caudata are primarily restricted to (a) terrestrial and (b) aquatic quadrupedal gaits and (c) undulatory swimming. Biologically accurate (d)

bio-inspired robotics have been developed to replicate and further understand Caudata locomotor patterns

**Caudata Locomotion, Fig. 2** “Hildebrand” plot displaying diagonality against hindlimb duty factor collected during quadrupedal walking in Caudata ( $n = 14$  species)

synonymous with the gait transitions observed in birds and mammals (Granatosky et al. 2018).

Unlike mammals and birds, *Caudata locomotion* is characterized by a sprawling posture (Ashley-Ross 1994; Ashley-Ross et al. 2009; Karakasiliotis et al. 2013; Nyakatura et al. 2019). Sprawling postures are those in which the humerus and femur cannot attain an orientation with their long axes vertically directed. Limb movements during sprawling gaits are complex and limb posture changes considerably during a stride cycle. Rather than moving in a fore-aft arc underneath the body, the humerus and femur move backwards, outwards and downwards during stance phase. For sprawling Caudata, the highly abducted limb and lateral rotation of the zeugopod relative to the autopod results in a kinematic arrangement in which the ankle and wrist flexor musculature are not in line with the travel path at the end of stance phase (Ashley-Ross 1994; Karakasiliotis et al. 2016; Nyakatura et al. 2019).

Lateral body undulation plays an important part in *Caudata locomotion* and is integrated with limb movement (Karakasiliotis 2013). Standing wave patterns, where points of no lateral bending nodes alternate with areas of maximal

bending internodes, are clearly present during terrestrial walking (Karakasiliotis et al. 2016; Nyakatura et al. 2019). At the start of a stride, the trunk between the forelimb and hindlimb is maximally displaced to one side, although lateral trunk displacement is substantially less than during aquatic swimming (see below), while the neck, head, tail are maximally displaced in the opposite direction. About halfway into the cycle, the trunk bends maximally in the opposite direction, forming a mirror image of the start of the cycle. Hence, during terrestrial walking, the body axis forms a single standing arc that undergoes one full oscillation during a locomotor cycle (Frolich and Biewener 1992).

The Caudata larval stage is entirely aquatic. Like the adults, these larvae have relatively elongate slender bodies making them closer in appearance to certain fishes rather than the short globular anuran tadpoles (Frolich and Biewener 1992; Hoff et al. 1989). Also, they are ambush predators like many fishes rather than herbivores like tadpoles (Hoff et al. 1989; Stebbins and Cohen 1997). However, Caudata larvae have exposed gills and well-developed limbs throughout most of their larval stage that distinguish them from fishes, and these limbs interfere with their swimming performance. In general, salamander larvae do not swim in a straight path at a constant velocity nearly as effectively as either tadpoles or fishes. They have far greater maximum amplitude at high swimming speeds, and far less anterior stability. The drag induced by exposed gills and limbs may account in part for the inferior performance of the salamanders (Hoff et al. 1989). The Caudata larvae are designed for movement among the rocks and vegetation of the substrate, and for high acceleration over short distances, such as those used during a lunge at prey (Duellman and Trueb 1994; Stebbins and Cohen 1997).

For adults, aquatic locomotion involves both walking and swimming gaits (Ashley-Ross et al. 2009; Frolich and Biewener 1992; Stebbins and Cohen 1997). Kinematics of aquatic walking appear to be largely similar to what is observed on land (Ashley-Ross et al. 2009). Therefore, this chapter will not discuss these gait kinematics in further detail. However, swimming represents a

substantially differing motor pattern (Ashley-Ross et al. 2009; Frolich and Biewener 1992; Ijspeert and Cabelguen 2006; Karakasiliotis et al. 2016; Karakasiliotis et al. 2013). During swimming, individuals tuck arms and legs close to the body and use a traveling wave of lateral undulation (Ashley-Ross et al. 2009; Frolich and Biewener 1992; Ijspeert and Cabelguen 2006; Karakasiliotis et al. 2016). The propagation of this traveling wave can be clearly seen by the timing of maximal lateral displacements along the length of the trunk during a locomotor cycle. Maximal lateral displacements of the trunk tend to be dramatically higher during swimming compared to either terrestrial or aquatic walking. As the locomotor cycle begins, a wave of maximal lateral displacement is initiated on the right side near the shoulder girdle. This wave then travels with a constant velocity down the right side of the animal. As the locomotor cycle progresses, this right-side wave reaches a position posterior to the forelimbs and a new wave is initiated on the left side. As the next locomotor cycle begins, the first right-side wave is at the base of the tail, the left-side wave has reached the anterior region of the trunk, and a new wave is initiated on the right side. This pattern is repeated with waves passing alternately down the right and left sides of the animal (Frolich and Biewener 1992). As a result, the body axis is always thrown into an S-shaped curve that travels down the animal. Some Caudata species, such as sirens and amphiumas, have reduced or absent hindlimbs and become fully aquatic. As such, this undulatory locomotor mode is their primary means of movement (Gillis 1997).

### Influence of Caudata Locomotion on Neuromechanics and Bio-inspired Robotics

*Caudata locomotion* has served as a model system for understanding the function of central pattern generators (CPGs), which are networks of neural circuitry that receive a single input signal and output a cyclical or rhythmic motor command in response. Locomotor CPGs generate from

within the spinal cord as opposed to the brain (Andersson et al. 1981; Golubitsky et al. 1999; Kiehn and Butt 2003) and are found in nearly all vertebrate species (Golubitsky et al. 1999; Grillner and Zangger 1975; Grillner 1975; Guertin 2009). These neural networks result in rhythmic activities such as walking, running, swimming, and even chewing. Activation of salamander CPGs display rhythmic movements in both walking, trotting, and swimming as muscle activation travels from head to tail and between the left and right sides of the body (Ijspeert 2008; Ijspeert and Cabelguen 2006; Karakasiliotis et al. 2013; Knüsel et al. 2013). Sensory feedback in salamanders are instrumental for gait transition dynamics, where proprioceptive sensory inputs were essential for walking gait sequences, as opposed to trotting gait sequences which rely more on central CPG influence (Harischandra et al. 2011). Gait transition between the two may be induced by increasing activity of the descending drive originating from the mesencephalic locomotor region and can be aided by sensory inputs at the forelimb and hindlimb regions of the spinal cord. Progressively increasing the drive signal from a frequency of about 5 Hz to 20 Hz in mechanical models of salamanders with artificial mesencephalic locomotor regions has been shown to result in a transition from walking to swimming (Ijspeert et al. 2007).

The information derived from salamander CPGs has served as the foundation to develop bio-inspired salamander robots (Fig. 1). Most notable is Pleruobot developed by Karakasiliotis et al. (2016) to model the terrestrial and aquatic locomotor mechanics of the Iberian ribbed newt (*Pleurodeles waltl*). Pleruobot's kinematics and anatomical scaling were inspired from biplanar cineradiography and high resolution micro computed tomography. Through these data, the degrees of freedom of the live animal's musculoskeletal system were reduced in complexity to only the most essential and influential connections and joints. As a result, Pleruobot can achieve biological accurate terrestrial and aquatic locomotor mechanics with only 27° of freedom distributed throughout the spine, limbs, and two free

unactuated joints (Ijspeert et al. 2007; Karakasiliotis et al. 2016).

Beyond just accurately recreating the locomotor movement and timing of Iberian ribbed newts, Pleurobot has been designed in a manner to replicate a functioning CPG (Harischandra et al. 2011; Ijspeert 2008; Ijspeert et al. 2007; Knüsel et al. 2013). From live-animal experiments, limb and spine kinematics were coded into the CPG and sent to the servomotors powering Pleurobot (Karakasiliotis et al. 2016). Pleurobot's CPG has served a vital role in coordinating timing, efficiency, and accuracy of servomotor movements using incremental continuous rather than discrete input stimuli (Ijspeert 2008). Such a system allows Pleurobot to make gait transitions between terrestrial and aquatic mediums (Ijspeert and Cabelguen 2006), while maintaining biologically relevant internal and external limb forces, joint kinematics, and spatiotemporal gait characteristics (Karakasiliotis et al. 2016). Bio-inspired robotics allows researchers to alter aspects of the anatomy and motor control and directly assess how these changes alter overall system performance. Such manipulation is not possible with living animals.

## Caudata Sensory Systems

Ellen M. Dawley

Ursinus College, Collegeville, PA, USA

## Synonyms

Caudata; Caudate; Urodela

## Introduction

Amphibians in the Order Caudata (or Urodela, salamanders, and newts) have the basic vertebrate senses that utilize the same receptor cells that are organized in the same basic patterns as all other vertebrates. This chapter is organized by receptor cell types: (1) Mechanosensory hair cells, which populate the inner ear or are located in structures embedded in the skin; (2) Olfactory/vomeronal chemoreceptor cells located in the nasal cavity; (3) Taste chemoreceptor cells located in the oropharynx; (4) Photoreceptor cells in eyes and parietal organ; and (5) Cutaneous receptors. Life cycles differ among caudates. Some species are aquatic both as larvae and adults; some are aquatic as larvae and terrestrial as adults; and some have the larval stage completed within the egg and hatch in terrestrial form (they are direct developers). Such distinctions affect the morphology and function of the different sensory systems. The large cell sizes of caudates also affect sensory system structure. Cell size affects number of receptor cells and subsequent organization of sensory organs and their targets in the central nervous system (Roth et al. 1992).

## Mechanosensory System: Body Position and Movement, Hearing, Lateral Line, Ampullary Organs

Mechanosensory hair cells are the sensory cells in all inner ear regions, lateral line neuromast organs, and ampullary organs of salamanders. The apical

surface (surface at the top) of hair cells has a cluster of stereocilia (stereovilli) arranged in a graded series by height, with the tallest adjacent to a single kinocilium (a true cilium), and the tip of each stereocilium is connected to the next higher stereocilium, and the tallest to the kinocilium, by structures called tip links (Fig. 1a). Tip links at the shorter of each stereocilia insert into a mechanically gated cation channel. If the kinocilium is deflected away from the stereocilia, tips links on adjacent stereocilia are tightened and cation channels on the stereocilia open, allowing cations, particularly potassium and calcium, to flow into the hair cell. This depolarizes the hair cell, ultimately causing excitation of the neuron that synapses with it. If the kinocilium is deflected in the opposite direction (toward the stereocilia), all tip links relax, closing the channels, which hyperpolarizes the cell, causing neuronal inhibition.

### Sense Organs of the Inner Ear

Mechanosensory hair cells are distributed in sensory patches within the inner ear, which is a membranous labyrinth of sacs and ducts, filled with endolymph (Fig. 1b). The membranous labyrinth is completely or partially encased within the cartilage or bone of the otic capsule of the skull, although there is a periotic labyrinth between it and the otic capsule (described further in section “Additional Structures Involved in Hearing: The Periotic Labyrinth”). The dorsal (superior) part of the membranous labyrinth is an elongated sac (utricle) from which the three semicircular canals emerge. The sensory patch of the utricle (macula) is overlain by a gel matrix with calcite crystals (otoliths). Movements of the endolymph cause the gel-otolith cap into which the stereocilia project to move, which then cause the stereocilia to bend. The utricular macula, which is set in a horizontal plane, measures position in space with respect to

**Caudata Sensory Systems, Fig. 1** Components of the caudate ear: (a) Mechanosensory hair cell with insert showing tip links that connect one stereocilium to adjacent stereocilia or to the kinocilium. The basal surface of the hair cell (opposite the apical surface) is where synapses are located. Small and large arrows in (f) show direction of sound pressure displacement, which ultimately exits otic capsule to the cranial cavity. (Adapted from Capshaw and Soares 2016)

gravity and linear acceleration (it is gravistatic, responding to gravity). Each of the semicircular canals has an ampullary enlargement that contains a sensory patch covered by a gelatinous cupula (ampullary cristae). Each detects angular acceleration in a different plane through movements of the endolymph against the crista.

Ventral (inferior) and connected to the utricle is the largest chamber of the entire labyrinth, the saccule, which contains another gravistatic macula and three recesses. Each recess has its own hair cell sensory patch. In salamanders, these recesses are: (1) the lagena with its gravistatic macula, (2) a recess located near the opening of the lagena that houses the basilar papilla, and (3) a recess that houses the amphibian papilla. Note that in total there are three gravistatic maculae: the utricular macula, the saccular macula, and the lagenar macula. The basilar and amphibian papillae are small hair cell patches each overlain by a gelatinous tectorial membrane (which is more sensitive than the gel-otolith cap of gravistatic maculae) into which the stereocilia project. Both papillae respond to sound waves. In comparison to amniotes (Reptiles, including Birds, and Mammals), which have only a basilar papilla, amphibians have two sensory organs for sounds, although the basilar papilla can be reduced or absent in some salamanders. Thus, the amphibian papilla is considered the primary auditory organ. Neurons from the 8th cranial nerve carry all sensory information from the inner ear to the medulla.

### Additional Structures Involved in Hearing: The Middle Ear

Most terrestrial Vertebrates have middle ear structures that transfer sound pressure waves from the air with low resistance to movement to the incompressible fluid of the inner ear. These terrestrial innovations include a large diameter tympanic membrane connected to one or more middle ear ossicles within a middle ear cavity, which insert into a small diameter oval window (the opening of the otic capsule to the periotic labyrinth surrounding the membranous labyrinth).

Among Amphibians, although most anurans (frogs) have large tympanic membranes and

a middle ear cavity, salamanders lack both. This means that sound passes through tissue to cause the less responsive middle ear ossicle (embedded in tissue rather than within a middle ear cavity) to move. There are two amphibian middle ear ossicles, a stapes (columella), which is homologous to the stapes of other terrestrial Vertebrates, and an operculum, which is present only in some species of postmetamorphic (juvenile and adult stages after metamorphosis) amphibians. Both ossicles, if present, insert into the oval window. The operculum is connected to the scapula by muscles, and proposed functions for this system include detection of airborne sounds or substrate vibrations, enhancement of vibrational sensitivity, protection against intense sounds, or modulation of frequency sensitivity. During caudate development, a stapes is the first middle ear element to form and is movable and functioning during the aquatic larval period (Fig. 1c). In species with aquatic adults that never metamorphose into terrestrial forms, only the stapes is present. In some caudate species with adults that spend some of their time on land, the stapes becomes fused to the otic capsule during metamorphosis and the operculum is the only movable element (Fig. 1d). In many terrestrial, direct developing species, only a stapes is present, which is connected to the scapula via muscles and functions like an operculum (Fig. 1e). These observations support the idea that a middle ear ossicle attached to the scapula via muscles is important for sound reception on land.

### Additional Structures Involved in Hearing: The Periotic Labyrinth

Another component necessary for perception of airborne sounds is a periotic labyrinth of ducts and sacs filled with perilymph, which occupies the spaces between the membranous labyrinth of the inner ear and the otic capsule. Thus, sound pressure waves drive the ossicle that inserts in the oval window, which then drives the perilymph in the cistern internal to the oval window through a pathway (periotic canal) that passes by the sensory patches of the amphibian and basilar papillae (Fig. 1f). This then sets into motion the tectorial membrane against the stereocilia. Among salamanders, the periotic labyrinth varies in pathways and

diameters of the periotic ducts, which likely corresponds to differences in how sound is directed toward sensory patches. In addition, the periotic ducts pass adjacent to the saccular and the lagenar maculae, suggesting that they may function in audition as well. Thorough reviews of caudate ear structure and evolution can be found in Hetherington (1988), Fritzsche and Neary (1998), Mason (2007), and Capshaw and Soares (2016).

### Auditory Abilities

Aquatic larvae and terrestrial adults appear to have similar abilities to hear underwater sound, substrate vibrations, and air-borne sounds. For both, sound underwater is detected through water borne vibrations transferred through the head and then middle ear ossicle to inner ear but may be enhanced in adults of some species via air induced pressure detection using air in the lungs. Substrate vibrations may be detected through the pectoral girdle linked to the operculum/stapes (adult) via muscles, and air borne sound waves may be detected using the middle ear ossicle, if air borne sound can cause the ossicle to move relative to the head. Nevertheless, hearing in air for caudates shows improved sensitivity and frequency range when compared to the abilities of fishes. This is likely due to structures not present in fishes: an oval window, a movable ossicle, and an amphibian papilla that uses a more sensitive tectorial membrane (Christensen et al. 2015).

### Lateral Line Organs and Electrosensory Ampullary Organs

Caudates also possess mechanosensory lateral line organs (neuromasts) that use hair cells as

receptors (Fritzsche and Neary 1998). Neuromasts are in the epidermis and consist of hair cell patches surrounded by support cells, capped with a gelatinous cupula into which the stereocilia project. The gelatinous cupulae extend into surrounding water. The neuromasts are arranged in three to four discrete lines along the body and along lower jaw, above and below the eye, and in the occipital region of head (Fig. 2). Neuromasts are stimulated by low frequency water movements parallel to the major axes of the lines (a kind of distant touch). Distinct lateral line nerves project to a dorsal nucleus within the medulla oblongata. Lateral lines are present in aquatic larvae and adults and may be retained during metamorphosis, although the neuromasts are often covered by skin when terrestrial and only some reappear when adults return to water. Lateral lines are lost in terrestrial, direct developing species. Lateral lines are used in foraging by aquatic forms and cave forms, and in avoiding predators. There is evidence in one caudate Family (Hynobiidae) that males respond to the tail undulations of other males, and sexually receptive females orient toward male tail undulations, through their lateral lines.

Ampullary organs are invaginations of the skin with a cluster of hair cells plus support and mantle cells around the base of the ampulla, and no cupula. They are sensitive to small changes in electric fields, like those emitted by small prey. They are found alongside the lateral lines of the head, except in terrestrial, direct developing species. Aquatic larvae and adults, particularly cave forms, rely on ampullary organs, in addition to lateral line organs and chemoreception.

**Caudata Sensory Systems, Fig. 2** Lateral line system in *Ambystoma*. (a) Lateral view, (b) ventral view. (Adapted from Kingsbury 1896)

## Olfactory/Vomeronasal Chemoreception

The caudate olfactory and vomeronasal sensory systems consist of epithelia (a thin layer of tissue) located in the nasal cavity that is composed of three cell types: olfactory receptor neurons, supporting cells, and basal cells, as is the situation in all Vertebrates (Fig. 3a). Underlying the epithelial layer is a region (lamina propria) often richly populated by various glands, particularly in terrestrial species. One of these gland types, Bowman's glands, supplies the surface of the olfactory epithelium of terrestrial vertebrates with a watery mucous solution containing odorant-binding proteins.

Olfactory/vomeronasal receptor neurons are bipolar, with a dendritic process that projects to the epithelial surface, which is studded with cilia or microvilli containing the receptor sites for odorant detection. Each receptor neuron expresses only one or few odorant receptor genes (ORG)

from a large family of ORGs (*Xenopus* frogs with 410 genes; mice with >1000 genes) or vomeronasal receptor genes (VRG), and individual genes are expressed in subpopulations of cells (Niimura and Nei 2006). ORGs/VRGs code for G-protein coupled receptors (GPCR) in the cell membrane, to which odorants bind, triggering a signaling cascade that subsequently leads to an action potential propagated through the axon. The axonal processes of receptor cells project to the main or accessory olfactory bulbs of the telencephalon (olfactory and vomeronasal, respectively). Supporting cells also possess microvilli; these cells have several glial-like functions and contribute to the overlying mucous layer. Basal cells are stem cells that produce new receptor neurons.

The paired nasal cavities (Fig. 3b) are dorso-ventrally compressed sacs (if terrestrial) or more tube-like (if aquatic), each with an external naris that opens into the main olfactory chamber, which

**Caudata Sensory Systems, Fig. 3** Caudate olfactory/vomeronasal systems: (a) Olfactory epithelium; (b) Olfactory and vomeronasal organs in place in *Plethodon cinereus*. b basal cells, bm basement membrane, bv blood vessel, en external nares, g Bowman's gland, in internal nares, ld lateral diverticulum housing the

is partly lined with olfactory epithelium (Reiss and Eisthen 2008). An internal naris exits into the buccal cavity. In aquatic larvae and adults, a nonsensory vestibule connects the external naris to the main chamber. Each main olfactory chamber has a lateral diverticulum (ventromedial in few species) that houses the vomeronasal organ, which is partly lined with a flat vomeronasal epithelium. In aquatic salamanders, whether larval or adult, the main chamber epithelium is ridged, with the olfactory epithelium confined to grooves between ridges. In terrestrial salamanders, the olfactory epithelium of the main chamber is a flat sheet of variable thickness, being thickest mid-dorsally and mid-ventrally, which positions the greatest number of olfactory receptor neurons in the pathway of greatest air flow during inhalation (Kauer 2002). In species that metamorphose from aquatic larvae to terrestrial adult, there are four major changes in the olfactory system: (1) the olfactory epithelium changes from ridged to flat, (2) which is accompanied by a changes in sensitivity of the epithelium from mainly water-borne odorants to include volatile odorants, (3) the shape of the main chamber changes from tube-like to a dorsoventrally flattened sac, and (4) the vestibule is lost. Both olfactory and vomeronasal receptors can be classified as to whether they detect air-borne or water-borne odorants, thus there is no support for the simple dichotomy that main olfactory receptors are specialized for air-borne odors and vomeronasal receptors for water-borne odors. However, there are different classes of ORGs/VRGs for either air-borne or water-borne odorants, but not both, and those that detect air-borne odors increased in the evolutionary transition from water to land (Niimura 2009; Niimura and Nei 2006). The vomeronasal organ is considered a tetrapod adaptation, which is lost in some aquatic species (Proteidae) but retained in most other species. Access to the vomeronasal organ has usually been shown to involve physical contact with an odor source, such as nose-tapping by salamanders in the Family Plethodontidae (the caudate Family that includes the majority of living species). Nose-tapping involves touching the upper lip with its nasolabial grooves (structure unique to plethodontids that convey

liquids preferentially to the vomeronasal organs) to an odor source. In plethodontid salamanders, the vomeronasal organ is more anteriorly situated, which directly connects the vomeronasal organ with the nasolabial grooves.

Several lines of research, particularly rich for species in the Families Salamandridae (Treer et al. 2013) and Plethodontidae (Houck 2009), have shown the importance of chemoreception in salamander social behavior. Studies of Red-backed Salamanders (*Plethodon cinereus*) have demonstrated that individuals can discern sex and species information, as well as familiar versus unfamiliar conspecifics through chemoreception. Territorial scent marking is accomplished using fecal pellets and secretions from unspecialized and specialized skin glands (post-cloacal glands pressed to the substrate), and nose-tapping is involved in odor sampling. Skin glands secretions can also function as sexual attractants, serving to locate potential mates. Modified glands of the cheek, chin, or cloaca produce pheromones that are wafted to or rubbed on female nares (Salamandrids) or inoculated in the skin or delivered to her nares (Plethodontids). Pheromones delivered to female nares were shown to specifically activate vomeronasal receptor neurons. These pheromones increase female receptivity to mating and then induce typical mating behaviors in females (Treer et al. 2013). These sorts of studies have fueled the notion that the vomeronasal system is more important than the main olfactory system in social interactions, particularly those involving pheromones, but other studies have shown that the olfactory system is involved as well. Based upon molecular analyses of salamander pheromones (Sodefrin Precursor-like Factor (SPF) system), it is thought that these pheromones likely date back to the earliest salamanders (Janssenswillen et al. 2014). Those living species that do not use these pheromones during courtship probably represent a loss of the pheromone character.

Olfactory/vomeronasal chemoreception is used in foraging, particularly for nocturnal or cave dwelling species with small eyes, including aquatic forms. Otherwise, vision predominates for adults of most salamander species. In addition,

salamanders, particularly larvae, avoid becoming prey by reacting to the chemical stimuli from predators by decreasing movement and spending more time in refuges.

## Taste Chemoreception

Taste receptor cells respond to only one of five basic tastes: sweet, savory (umami), bitter, sour, and salty, a model well supported by mammalian studies. The apical ends of the taste receptor cells, which end in microvilli, comprise the taste receptor area that interacts with taste molecules. Microvilli protrude above the surface of the epithelium in Amphibians (Fig. 4a, b). Taste molecules bind with receptor sites to trigger the transduction cascade (the conversion of the taste stimulus at the apical end of the cell to release of neurotransmitter at the taste cell-sensory neuron synapse), leading to taste recognition. Taste cells are innervated by branches of cranial nerves 7, 9, and 10 (facial, glossopharyngeal, and vagus), which project to the nucleus of the solitary tract located in the hindbrain. Sweet and umami receptors are part of a small family of G-protein-coupled receptors, and both trigger behavioral attraction. Bitter receptors belong to a different group of G-protein-coupled receptors and act to prevent ingestion. Sour and salty are both mediated by membrane channels. Although there have been molecular studies in fish to identify types of taste receptors, similar studies have not been done with caudates.

Information about taste reception in caudates has come from electrophysiological studies of transduction of taste stimuli, which provided evidence of the same five basic tastes in amphibians, although the ability to taste sweet may be lacking in caudates (Barlow 1998). Aquatic salamanders, specifically mudpuppies (*Necturus maculosus*) and larval tiger salamanders (*Ambystoma tigrinum*), have been the subjects of these studies of transduction mechanisms, but nothing is known about other species, particularly, those with terrestrial adult stages.

Amphibian taste receptor cells are grouped into units called taste buds (Fig. 4a) or taste disks (Fig. 4b), which are scattered throughout the oropharynx. Because caudate taste systems were first described in species that are aquatic even as adults, it was thought that caudates at all stages possess taste buds. In contrast, while aquatic larval anurans have taste buds, they metamorphose into adults with taste disks. More recent studies have shown that caudate species with terrestrial adult stages also have their taste receptor cells organized into structures that look more like taste disks. Taste buds are aggregates of cells arranged in a rosette, which may reside upon papillae (raised epithelium surrounded by a trench) or bulges or directly embedded in the epithelium within the oropharyngeal cavity. Taste disks are larger aggregates of cells with a broader receptive surface and with some different cell types than taste buds. They are also located in tongue papillae or directly embedded in epithelium.

### Caudata Sensory Systems,

**Fig. 4** Amphibian taste bud (a) and taste disk (b), based upon these structures in larval and adult *Salamandra salamandra* (Zuwala and Jakubowski 2001)

Taste receptor cells in both taste buds and taste disks are fusiform cells that extend the length of the bud or disk. Within taste buds there are also basal cells, which are disk-like cells that lie at the base of the bud. Some basal cells may have a neuromodulatory role with the receptor cells, and others likely are stem cells. Within taste disks, in addition to basal cells and receptor cells (and there are sometimes reported a glia-like cell), there are large mucus cells and uniquely shaped wing cells. Wing cell bodies lie beneath the mucus cells and their flattened apical processes separate the mucus cells. The mucus cells contribute to making the receptive surface broader than that of taste buds, and likely are adaptations to terrestriality (Zuwala and Jakubowski 2001).

A transition from taste buds to taste disks on the tongue and on the lining of the oropharynx occurs with metamorphosis. In the permanently aquatic, neotenic axolotl (*Ambystoma mexicanum*), taste buds in larvae are scattered over the surface (floor and roof) of oropharynx and they begin to erupt at hatching. They increase rapidly in number, reaching adult number by 10 weeks, and are highly concentrated on the lingual surfaces of lower and upper jaws, including the primary tongue, and less so on the visceral arches. In caudate species that have been examined that undergo metamorphosis (*Salamandra salamandra*, *Hynobius retardatus*, *H. dunni*, and *H. leechi*), the primary tongue with taste buds is replaced by a secondary tongue with taste disks,

and taste buds in the lining of the oropharynx are replaced by taste disks. In direct developing caudate species, taste buds never develop, and newly hatched young possess the adult secondary tongue with taste disks, as well as taste disks on the lining of the oropharynx (Budzik et al. 2016). In adults of these species, the tongue is densely covered with taste disks, as well as the palate and lingual surface of upper and lower jaws. The positions of taste buds or discs suggest that taste is used to sample potential food items as they are pulled into the mouth by suction or use of jaws and prehensile tongue. Hence it is likely that taste is used in rejecting food, and other senses (vision and olfaction) are important for finding food.

## Photoreception

Caudate eyes are composed of the same elements as are all vertebrate eyes. Here the deepest structures are described first followed by progressively more superficial structures (Fig. 5a). The sclera and choroid layers (both dense connective tissue) are external-most. The retina (Fig. 5b) is composed of five layers, with the photoreceptor layer located in the deepest layer (ONL, the outer nuclear layer), and followed a very thin outer plexiform layer (OPL) composed of synaptic contacts. A thick layer of interneurons, the inner nuclear layer (INL) composed of horizontal, bipolar, and amacrine cells, is found next, followed by

**Caudata Sensory Systems, Fig. 5** Caudate eye (a) and details of retina (b). (a, Adapted from a photograph of *Bolitoglossa subpalmata* Roth et al. 1998). (b, Adapted from Butler and Hodos 1996). *INL* inner nuclear layer, *IPL* inner plexiform layer, *ONL* outer nuclear layer, *OPL* outer plexiform layer, *PL* photoreceptor layer, *RGL* retinal ganglion cell layer

a thick inner plexiform layer (IPL) of synaptic contacts. The retina is capped with a retinal ganglion cell layer (RGL), whose axons coalesce to form the optic nerve that exits the eye to synapse with brain targets. The bipolar cells connect the photoreceptor cells to the ganglion cells, while horizontal and amacrine cells modulate activity in this pathway by coupling or uncoupling photoreceptors. Superficial to the retina is a relatively thin vitreous body, then a large lens, followed by a watery aqueous humor filling the spaces in front of the lens, and, finally, a large cornea occupying nearly 1/3 of the eye surface (Fig. 5a). The cornea, aqueous humor, lens, and vitreous body function to refract incoming light, focusing it on the retina. In terrestrial salamanders, the large, curved cornea is the main refractive apparatus, while aquatic salamanders have a flatter cornea, and the nearly spherical lens is the main refractive apparatus.

The two layered ONL contains both types of vertebrate photoreceptors, rods and cones (Sherry et al. 1998). Both rods and cones have two compartments, an outer segment that is composed of stacked discs that contain the visual pigment molecules and an inner segment with nuclei and terminal branches of the cell. The cells are oriented with the inner segment adjacent to the OPL, where the synapses between photoreceptor cells and bipolar cells are located. Visual pigment molecules consist of an opsin protein bound to a carotenoid chromophore (retinal) to form a G protein-coupled photopigment within the membranes of the stacked discs. Most rods contain the photopigment rhodopsin (opsin + retinal1, a derivative of vitamin A1) in terrestrial caudates, or porphyropsin (opsin + retinal2, a derivative of vitamin A2) in some aquatic species, with maximum absorbance in the green spectrum. In addition, certain caudate genera (*Hynobius* and *Ambystoma*) and anurans possess a second rod type, a blue sensitive rod (confusingly named green rod) in addition to the green sensitive (normal) rod. In some anurans, the blue sensitive rod allows them to distinguish blue and gray under dark conditions, but it is unclear whether the same is true for caudates because only the blue-sensitive cone pigment is expressed in both rods and cones, suggesting it could not function

under dim light. There are three types of cone opsins in caudates, with names reflecting their maximum spectral sensitivities: very short (VS or violet/ultraviolet), short (S, or blue), and long (L, or red), with the latter being the most common type. A medium (M, or green) cone opsin is missing. UV sensitivity may be widespread across caudates despite the assumption that UV vision should not be favored in animals that live under forest canopies, or under water, or are nocturnal (all describe caudates). In nocturnal caudates, rods are the most numerous photoreceptor.

Light absorbed by the photopigments of the rods and cones creates an electrical neural signal carried to the brain by the axons of the retinal ganglion cells (RGC). Since visual acuity is partly determined by the diameter and packing of rod/cone outer segments, a large number of small diameter rods and cones increases acuity. Caudates, especially plethodontids, because of their relatively small eyes but large cell sizes, have “astonishingly low” numbers of RGC axons (a count of number of RGCs within the optic nerve). Yet they have “excellent visual abilities” (Roth et al. 1998). Most optic nerve fibers cross at the optic chiasm to the opposite side of the brain, traveling as the optic tract. The superficial layer of the optic tectum (a mesencephalic structure) is the major target of retinal cell axons, where this sensory information is mapped in topographic order. The caudate optic tectum is organized into two zones (superficial and deep), compared to the nine layers of alternating fibers and cellular layers of anurans, which, itself, has fewer layers than the tecta of teleosts and reptiles. Amphibian visual systems are considered secondarily simplified, with cell size negatively correlated with complexity of the optic tectum (Roth et al. 1992).

And yet, for most caudates, vision is the major sense used in prey detection and capture. Prey size, speed, movement patterns, and shape are the major cues used by salamanders, who are able to fixate binocularly on prey; orient toward prey with eye, head, or body movements; walk toward prey or ambush them; snap and seize with mouth or, in some species, seize with a protrusible

tongue. While at night prey movement is the most important visual cue, stationary prey are recognized by size, shape, and orientation cues, and salamanders can even discriminate quantity via prey movement (Krusche et al. 2010). Many species have a large visual field, some covering 360°, because eyes are frontally oriented; species with more laterally placed eyes have a binocular field of 65°. The most spectacular visual feats are accomplished by bolitoglossine plethodontids (a large group of Neotropical species), which all have free, projectile tongues with a reach of up to 2/3 snout-vent length, which are faster and more precise than that of any other amphibian, despite the most simplified optic tectum. They have highly developed stereoscopic vision and several unique adaptations that compensate for reduced number of neurons in the visual system, including a 1:1 ratio of photoreceptors to RGCs, which converts the entire eye to a functional fovea (a depression in the retina with a high concentration of photoreceptors).

Vision is also important in interacting with other organisms, along with chemoreception. A wealth of research on *Plethodon cinereus* (e.g., Kohn and Jaeger 2009; Duhaime-Ross et al. 2013) has shown that individuals signal aggression or submission toward conspecifics via postures; mates may assort with each other based upon visual cues (red and lead phases); and they can use visual cues to escape from predators. Because many temperate zone amphibians are active at dusk, it has been suggested that color skin patches reflecting UV light may be used in sexual communication, which would explain why functional genes for very short opsins are widespread among caudates (Mege et al. 2016).

Caudates, like many nonmammalian vertebrates, possess an extraocular photosensory organ, the pineal organ, which is an extension of the dorsal diencephalon. It is an intracranial, sac-like structure composed of rod-like photoreceptor cells, support cells, and neurons (like RGCs) that send axons to targets in the brain (in this case, dorsal diencephalon). The photoreceptor cells possess a basal axon, and inner and outer segments, the latter segment with photopigments sensitive to short (likely UV) and medium

wavelengths. These photoreceptors are sensitive to the plane of polarized light, and thus mediate celestial compass orientation, but also are sensitive to earth-strength magnetic fields and thus serve as a magnetic compass (Phillips et al. 2010). Migrating newts (Eastern red spotted, alpine newts, palmate newts) have been shown to use magnetic cues during nocturnal homing. In addition, the pineal organ is part of the mechanism regulating the body lightening reaction in larval amphibians.

## Cutaneous Receptors

Cutaneous receptors are free or encapsulated nerve endings in the epidermis or dermis that respond to light and strong touch, injuries (pain), vibration, and temperature (Heatwole 1998). Their cell bodies reside in the spinal cord dorsal root ganglia, thus they are spinal nerves, or in the hindbrain and travel through the trigeminal cranial nerve to the head. The receptor potential is generated by mechanical deformation of the nerve plasma membrane. The few studies specifically about caudate cutaneous receptors have concentrated on the Rohan Beard cells of embryos and early larvae and the Merkel cell-neurite complex of larvae and adults. The cell bodies of Rohan Beard cells form quite early in development to populate the length of the dorsal spinal cord, sending processes to the skin. They detect transient touch stimuli, initiating swimming or struggling. Merkel cells are located in the epidermis and are distinguished by small, finger-like surface processes, cytoplasmic Merkel granules (membrane bound granules), and are associated with tactile sensory nerve fibers of spinal nerves. Merkel cell-neurite complexes function as low threshold, rapidly adapting mechanoreceptors, and perhaps are the only mechanoreceptors in caudate skin.

## Cecilia Heyes

Cecilia Heyes  
University of Oxford, Oxford, UK

Cecilia Heyes, known as “Celia,” was born and brought up in Ashford, a small town in the southeast of England where her grandparents had worked on the railways and, in the surrounding countryside, as gamekeepers and domestic servants. The first member of her family to go to university, she chose to study psychology because she wanted to work in mental health, but her head was turned to the evolution of cognition by the inspirational lectures of Henry

Plotkin. After studying for a PhD at University College London (1981–1984), under Plotkin’s supervision, she was awarded a Harkness Fellowship to work for 2 years in the United States with the distinguished social psychologist Donald Campbell at Lehigh University and with two philosophers: William Wimsatt at the University of Chicago and Daniel Dennett at Tufts University in Boston. During a second period of postdoctoral study, as a Research Fellow at Trinity Hall, University of Cambridge (1986–1989), she was adopted by the laboratory of Anthony Dickinson and Nicholas Mackintosh, experts on associative learning. Their research tradition, animal learning theory, was diametrically opposed to the evolutionary approaches in which she had marinated before going to Cambridge. After 5 years of theory and nature, she learned the importance of experiments and the power of nurture. By the time she returned to University College London, now as a member of faculty, Heyes had been educated into a state of deep, rich confusion. She wanted to know more about how nature and nurture work together to build minds but had no idea how to find out. In retrospect, Heyes’s research over the next 30 years – at University College London (1988–2008) and then at All Souls College, University of Oxford (2008–present) – makes sense in the light of that ambition, but there was no grand plan. At any given time, she felt as if she was following her nose, being pragmatic enough to get research funding, taking opportunities provided by gifted students and postdocs, and hoping she would not be ejected from the wonderful but demanding world of academic research.

Heyes has focused on social cognition, principally social learning, imitation, mirror neurons, and theory of mind. She has done experimental work with nonhuman animals (rodents and birds), with adult humans (neurotypical and people with autism), and, in collaboration, with human infants and children. She has also published synthetic theoretical work on nonhuman primates and on broader themes relating to the evolution of human cognition. Although firmly rooted in experimental psychology, Heyes’s research also draws on behavioral economics, evolutionary biology,

neuroscience, philosophy of mind, and philosophy of science.

When Heyes began her research in the 1980s, it was widely believed that social learning – learning assisted by other agents – depends on psychological processes distinct from those enabling asocial learning and that the mechanisms of social learning had evolved specifically to enable transfer of information between agents. Heyes contested this view initially for non-imitative forms of social learning; cases in which one agent learns through interaction with another (e.g., about the location of food, or what to eat), but the learner does not copy movement topography – the way in which parts of the actor’s body move relative to one another (e.g., the model’s gait or foraging technique). She did this in two ways. First, in a wide-ranging conceptual analysis and empirical review of the literature on social learning, reaching back to the beginning of the twentieth century, she showed that each known type of social learning (e.g., stimulus enhancement, observational conditioning, imitation) corresponds with a known type of asocial learning (Heyes 1994). Second, developing new empirical methods (the “two-action test” and “ghost control”; Fawcett et al. 2002; Heyes et al. 1994; Heyes and Saggerson 2002), Heyes’s group completed a program of experimental work with rodents and birds showing that animal learning theory could provide mechanistic explanations for a broad range of social learning effects. At the beginning there was a good deal of resistance to Heyes domain-general analysis of social learning, but it is now widely accepted that most, if not all, social learning in animals is mediated by the same core mechanisms as asocial learning. The “social” part of social learning is attentional; the psychological processes that encode information for long-term storage are the same whether the input is from the social or inanimate world (Heyes 2012a).

Initially, Heyes accepted the view, established by Edward Thorndike in the late nineteenth century, that imitation is special. An early and influential article (Heyes 1993) queried the assumption that imitation is especially important for the cultural inheritance of information but acknowledged that no mechanistic solution had been found, in learning theory or elsewhere, for

imitation’s “correspondence problem.” This problem, explicated by Jean Piaget, is roughly: When imitators cannot see their own movements, how does the cognitive system convert visual input from a model into motor output that is topographically similar to the model’s behavior from a third-party perspective? More pithily: How does the cognitive system convert the seen but unfelt into the felt but unseen (Meltzoff and Moore 1997).

Starting in 2000, Heyes took up this explanatory challenge (Heyes and Ray 2000; Heyes 2001; Catmur et al. 2009). Her associative sequence learning (ASL) model of imitation proposes that the correspondence problem is solved by bidirectional excitatory links between visual and motor representations of the same actions and, crucially, that these links, or “matching vertical associations,” are forged through social interaction in the course of childhood. Synchronous drills and games, exposure to optical mirrors, and imitation of infants by adults provide correlated experience of seeing and doing the same action and thereby build the repertoire of matching vertical associations that gear motor sequence learning to perceptual sequence learning processes to make imitation possible.

Shortly after the ASL model was first published, Heyes applied it to mirror neurons – individual neurons that discharge when an action, e.g., grasping, is performed and when the same action is observed (Gallese et al. 1996). She opposed the consensus view that the visuomotor properties of mirror neurons are an adaptation produced by natural selection operating on genetic variants. In contrast, her analysis suggests that mirror neurons start out as ordinary motor neurons and become connected to corresponding visual neurons through associative learning in the context of self-observation and specified types of social interaction.

Some of Heyes’s most outstanding empirical work has tested her ASL model of imitation and mirror neurons. In studies of nonhuman animals, her group showed that budgerigars are capable of imitating body movements as well as vocalizations (Mottley and Heyes 2003; Richards et al. 2009) and that like humans, birds

(Mui et al. 2008), and dogs (Range et al. 2011) engage in automatic as well as goal-directed imitation. Using behavioral (“automatic imitation”) and neurophysiological methods (electromyography, functional magnetic resonance imaging, transcranial magnetic stimulation) with adult humans, her group showed that imitation and mirror neurons are highly plastic. As the ASL model predicts, imitative tendencies and mirror effects can be induced, enhanced, abolished, and reversed by novel visuomotor experience (Cook et al. 2014; Heyes 2010). For example, motor-evoked potentials recorded from the hand indicate selective activation of muscles controlling the little finger during observation of little finger abduction and of muscles controlling the index finger during observation of index finger abduction. However, this mirror effect can be reversed by training in which subjects respond to little finger movements with index finger movements and vice versa (Catmur et al. 2007), and this counter-mirror effect depends on the same areas of premotor cortex as those responsible for the original mirror effect (Catmur et al. 2011).

Alongside her work on social learning, imitation, and mirror neurons, Heyes has taken a lively interest in another aspect of social cognition – theory of mind (also known as “mindreading” and “mentalizing”). A target article in the *Behavioral and Brain Sciences* (Heyes 1998) offered a conceptual framework for research on theory of mind in nonhuman primates, argued that research to date provided no compelling evidence that nonhuman primates can ascribe mental states, and laid out a new experimental strategy with the power to provide evidence that nonlinguistic subjects can ascribe “seeing” to another agent. This strategy, the “goggles procedure,” has now been used many times with human children, where it has confirmed mental state ascription, and with nonhuman primates, where it has not. In later work on theory of mind, Heyes provided a detailed critique of research purporting to show that young infants can ascribe false beliefs (Heyes 2014a) and argued that much of the implicit or automatic mentalizing reported in adults is due to domain-general “submentalizing” (Heyes 2014b).

Because Heyes offers lean, mechanistic explanations for behavior, she has a reputation as a critic among some primatologists and

developmental psychologists. This complaint was never wholly convincing because her critical work was always accompanied by specific alternative hypotheses, proposals for how those hypotheses could be tested against the received view and, in many cases, new data reporting the outcomes of such tests (Heyes 2012b). However, the constructive breadth and originality of her thinking did not become fully apparent until the 2010s when she began publishing a series of articles (e.g., Heyes 2012c, 2016a; Heyes and Frith 2014), and ultimately a book (Heyes 2018a, 2019a), on the cultural evolution of human cognition. This work integrates cognitive science with cultural evolutionary theory for the first time. Previously, cultural evolutionists – mostly biologists, anthropologists, and mathematicians – had blackboxed cognition (Heyes 2016b). They concerned themselves with observable behavior and everyday characterizations of the mind. By bringing computational cognitive science to cultural evolutionary theory, and vice versa (Heyes 2018b), Heyes offered a radical, empirically grounded alternative to traditional evolutionary psychology. Her “cultural evolutionary psychology” focuses on distinctively human cognitive mechanisms; domain-specific processes – such as mentalizing, imitation, moral cognition (Heyes 2019b), and explicit metacognition (Heyes et al. 2020) – which are absent in other animals or present there only in some nascent form. It marshals evidence that, although their development is supported by a genetic “starter kit” (Frith 2001), these mechanisms are inherited socially rather than genetically, and they have been made fit for purpose primarily by natural selection acting on cultural rather than genetic variants. They are, in her terms, not “cognitive instincts” (Pinker 1994) but “cognitive gadgets.”

Heyes is a Fellow of the British Academy – the UK’s national academy for the humanities and social sciences – and a Past President of the UK’s Experimental Psychology Society.

Hofstra University, Hewlett, NY, USA

The cell membrane is also referred to as the plasma or cytoplasmic membrane. It is a membrane that encloses every cell in order to differentiate between the inner cell contents and the outer cellular environment. This is the outermost layer in animal cells. However, bacteria, fungi, and plants contain a layer beyond the plasma membrane (known as the cell wall) which in addition to cell support also prevents large molecules from diffusing in (Yawata 2003).

### Structure and Function

The cell membrane is approximately 7.5–10 nm (Nano is  $10^{-9}$  m) thick and is composed of a phospholipid bilayer (Yawata 2003). Hence, the membrane contains two layers of multiple phospholipids aligned across from each other. Each phospholipid contains a phosphate head and two lipid (fatty acid or oil) tails. The tails are all oriented inside and the phosphate heads stick out in forming the lipid bilayer (Fig. 1).

The lipids are rod-shaped and hydrophobic (water repelling). The phosphate head groups are hydrophilic (attracting water). This results in the membrane's selective permeability which allows specific molecules to diffuse through at different rates (Lombard 2014).

The movement of molecules can either be active or passive, which either requires an input of energy or does not, respectively.

### Proteins and Gases in the Membrane

A number of proteins can be found embedded within the membrane and interacting with the respective hydrophobic and hydrophilic positions (Lombard 2014). Likewise, the lipid

bilayer acts as a fluid mosaic at physiological temperature, which allows for the phospholipids and proteins to move about the bilayer which is each composed of differing phospholipids. Furthermore, cholesterol are biological molecules that aid in the membrane rigidity of the cell (Lehninger et al. 2008). Overall there are four major components to the fluid mosaic phospholipid bilayer, cholesterol, proteins, and carbohydrates.

Gases are allowed free exchange across the membrane because they are lipid soluble, such as oxygen ( $O_2$ ) and carbon dioxide ( $CO_2$ ) (Lehninger et al. 2008).

### Protein Channels in the Membrane

Protein channels are also allowed free movement about the membrane. There are varying types of protein channels which are specific to the content they allow to diffuse in and out of the membrane. This type of diffusion is known as active diffusion because it provides the energy needed to diffuse the otherwise nonpermeable molecule. In other words, these protein channels are essentially pumps that allow material to be exchanged from inside and outside of the cell, thereby providing the essential nutrients to the cell and expelling the wastes (Lehninger et al. 2008).

A receptor protein is activated by a specific molecule, known as an antigen. This antigen binds to the receptor protein outside of the membrane bilayer and causes a signal to be trickled down into the cell. Each antigen is specific to one receptor and carries only one message such as letting the cell know to prepare for cell division, metabolize glucose (sugar) into energy if it is low in the body, gene expression, etc. A channel protein is always open and allows a specific molecule to enter and leave the cell freely based upon concentration gradients. A gated channel protein works as a pump, to pump ions across their concentration gradients ( $Na^+$ ,  $K^+$ ,  $Ca^{+2}$ , and  $Cl^-$ ) in response to a chemical messenger such as a ligand which binds to it on the extracellular or intracellular matrix. Transport proteins (integral

**Cell Membrane, Fig. 1** Cell membrane components: phospholipid bilayer, cholesterol, proteins, and carbohydrate groups (Created using ChemDraw)

membrane proteins) are proteins that span across the entire membrane and allow molecules to pass through via facilitated diffusion (active diffusion). Lastly, glycoproteins are proteins with a carbohydrate chain attached to them (via glycosylation) that function to stabilize the membrane via hydrogen bonds with the extracellular environment (Miller and Levine 2008).

## Definition

The most recent era of the earth's history, which began 65.5 million years ago (mya), is known as the "Cenozoic Era." This is that time frame in which the geological changes gave rise to the world map's current face, and the biological changes enriched it with today's flora and fauna. Despite representing only 1.4% of the earth's history, comprehensive knowledge is available pertaining to this era.

## Introduction

Cenozoic, spelled initially as Kaniozoic, means “recent life” as newer forms of life, similar to the present-day biota appeared during this era. Cenozoic derives its name from two Greek words *kainós*, meaning “new,” and *zoic*, meaning “animal life” (Harland et al. 1990). British geologist John Phillips coined the term in the year 1840.

Anthropologically, Cenozoic is significant because the entire primate evolution and the subsequent human evolution occurred during this era. Besides primates, other mammals, birds, most flowering plants, and grasses experienced substantial evolutionary radiation during this phase of the earth’s history.

## The Beginning of the Cenozoic Era

This most recent subdivision of the Phanerozoic Eon is supposed to have begun about 65.5 mya, at the Cretaceous-Paleogene (K-Pg) boundary, marked by a catastrophic extinction event. This devastation led to the extermination of 75% of the life on earth, including the non-avian dinosaurs.

The reason for this extinction event has been a subject of debate for a very long time (Brusatte et al. 2015). The most widely accepted theory is the catastrophic impact from an asteroid (10 km diameter), which created the Chicxulub crater in Yucatan, Mexico. The effect is proposed to have thrown enormous dust into the atmosphere, blocking sunlight (for about a year), setting in a prolonged winter, killing the flora, suppressing the potential global dinosaur habitats, and subsequently leading the dinosaurs to extinction (Chiarenza et al. 2020). The presence of iridium, a rare earth metal but more common in meteors and asteroids in the K-Pg boundary, further supports the theory.

Some researchers propose Deccan volcanism as the main abiotic driver of the K-Pg mass extinction (Keller et al. 2011). Rapid and massive volcanic CO<sub>2</sub> and SO<sub>2</sub> emissions appear to have caused acid rains, high continental weathering, global warming, ocean acidification, and a carbon

crisis in the marine environment, ultimately leading to the dinosaurs’ extinction.

Post dinosaur extinction, vacant ecological niches were occupied and exploited by other life forms, especially mammals, which flourished and diversified across the globe. For this reason, the Cenozoic Era is also known as the “Age of Mammals.”

## The Cenozoic Timescale

In 2009, the International Union of Geological Sciences (IUGS) formally adopted the division of the Cenozoic Era into three periods, namely, the Paleogene (65.5–23 mya), the Neogene (23–2.6 mya), and the Quaternary (2.6 mya to the present). The Paleogene (*palaiós* = old + *genes* = born) is subdivided into three epochs – the Paleocene (65.5–55.8 mya), the Eocene (55.8–33.9 mya), and the Oligocene (33.9–23.03 mya). The Neogene (*neo* = new + *genes* = born) period comprises two epochs – the Miocene (23.03–5.332 mya) and the Pliocene (5.332–2.588 mya). The Quaternary includes two epochs – the Pleistocene (2.588–11,700 years ago) and the Holocene (11,700 years ago to the present).

## Cenozoic Events in a Chronological Order

### Paleocene (65.5–55.8 mya)

The Paleocene derives its name from the Greek words *palaiós* = old and *kainós* = new, referring to the organisms that survived the K-Pg extinction and subsequently evolved into the primitive forms of the modern lineages.

Forming the base of the Cenozoic, the Paleocene saw the surviving mammals grow in size and number and diversify into rodent-like mammals, scavenging medium-sized mammals, and large herbivorous and carnivorous mammals. These mammals evolved bigger, became more ferocious, and spread throughout the world as the dominant predators.

The Paleocene is subdivided into three stages, the Danian (65.5–61.7 mya), the Selandian (61.7–59.2 mya), and the Thanetian (59.2–55.8 mya).

#### Paleocene Fauna

**Mammals:** Due to the paucity of fossil evidence, relatively little is known about the Paleocene mammals. The few lineages that survived the K-Pg extinction, primarily consisting of small nocturnal herbivores and insectivores occupying a limited number of ecological niches, were suddenly free to fill the void. Most of these Paleocene mammals belonged to the primitive (or archaic) groups and included the following:

- Monotremes – egg-laying mammals such as *Monotrematum*, a relative of the platypus.
- Marsupials – pouched mammals such as opossum.
- Multituberculates – an extinct group of herbivorous animals with rodent-like teeth, which were the most successful Mesozoic mammals.
- Placentals – mammals with a reproductive system that allows the fetus to develop entirely within the female before birth. They became the most diverse and successful group of mammals consisting of the following:
  - Condylarths – hoofed animals that evolved toward herbivory while still retaining insectivorous-carnivorous traits.
  - Primates – mammals that displayed characteristics intermediary of insectivores and lemurs. They became abundant in the middle Paleocene.
  - Creodonts – catlike and doglike primitive carnivores.

The fossil records document explosive adaptive radiation of mammals characterized by a dramatic increase in therian mammals' diversity (including the marsupials and placentals).

**Birds:** The global destruction of forests associated with the K-Pg event served as a strict filter against the tree-dwelling stem birds. The ground-dwelling crown birds that survived

the holocaust rapidly diversified and gave rise to the modern tree-dwelling birds (Daniel et al. 2018).

**Reptiles:** While the non-avian dinosaurs and large marine reptiles became extinct at the end of the Cretaceous, ancestors of modern reptiles not only survived through the K-Pg boundary but also underwent great adaptive radiations into turtles, lizards, crocodiles, and snakes.

**Amphibians:** These, which originated during the Jurassic, were not much affected by the holocaust. Giant salamanders, hellbenders, aquatic salamanders, New World frog, and real toads appeared during the Paleocene.

#### Paleocene Oceans

It took millions of years for life to recover in the early Paleocene oceans following the mass extinction event. The primary producers, diatoms, dinoflagellates, and coccolithophores, which experienced a significant setback, underwent adaptive radiations during Paleocene and regained their pre-K-Pg diversity. The reef systems that collapsed in the extinction event recovered very slowly and diversified after eight million years. By the late Paleocene, multiple groups of marine invertebrates diversified from the Mesozoic survivors. Marine fauna more or less resembled modern fauna, with sharks becoming the top predators.

#### Paleocene Flora

The plant fossil records and asteroid impact models provide strong evidence for the devastation of forests at the K-Pg boundary. In the initial phase of disruption, the energy dissipated by the impact could have released intense heat, igniting wildfires at a global scale and destroying vegetation in a diameter of 1,500 km. The next phase of disruption possibly included the release of sulfate-rich vapors that resulted in acid rain, destroying vegetation. Ejection of enormous soot potentially blocked photosynthesis for several years and induced global cooling. Suppression of sunlight delayed the recovery of forests and perhaps led to the proliferation of saprotrophs (Daniel et al. 2018).

Postimpact recovery of flora occurred in two phases. The first phase saw a fern spike, with ferns, the pioneer species of devastated landscapes, becoming dominant over the surviving angiosperms and conifers. This “fern spike” is seen in the terrestrial Paleocene strata, immediately overlying the K-T boundary (Stanley 2001).

The second phase was marked by the re-establishment of canopy vegetation dominated by new angiosperms and conifers characterized by low taxonomic diversity. The Paleocene saw the evolution of modern plant species, including the cacti and palm trees. The warm global temperatures favored tropical, subtropical, and deciduous forests worldwide. Interestingly, the ice-free polar regions were covered with dense coniferous and deciduous trees.

#### Paleogeography

During the Paleocene, the shape of continents was similar to that of the present day, but they were in different positions. Laurasia and Gondwanaland, the supercontinents in the northern and southern hemispheres, respectively, began drifting to their present-day positions. The Gondwanaland components moved apart from each other forming Africa, South America, Antarctica, and Australia. In comparison, the components of Laurasia drifted apart to form North America, Europe, and Asia.

North America and Asia were still interconnected by the land bridge, while Greenland began to separate from North America. Equatorial seas separated South America and North America. Africa and India started drifting northward, slowly closing in the Tethys Ocean. In western America, the Laramide orogeny that began in the late Cretaceous uplifted the Rocky Mountains.

#### Paleoclimate

During the Paleocene, the earth gradually became warmer and more humid, showing a global warming trend. The climate was completely different then, with no polar ice caps and a cold temperate climate. Equatorial areas had tropical climates; the lower latitudes were hot and arid, while the continents in higher latitudes were warm with temperate climate.

#### Eocene (55.8–33.9 mya)

The Eocene derives its name from the Greek words *eos* = dawn and *kainós* = new, meaning the appearance of modern fauna. It is generally divided into the Early (56–47 mya), Middle (47.8–38 mya), and Late (38–33.9 mya) Eocene. The Eocene is formally subdivided into the Ypresian (56–47.8 mya), Lutetian (47.8–41.3 mya), Bartonian (41.3–38 mya), and Priabonian (38–33.9 mya) based on the characteristic rocks.

Around 56 mya, when the earth was entering the Eocene Epoch, the gradual warming trend reached a tilt point, and the global temperatures surged by about 5 °C within just 20,000 years. This event, known as the Paleocene-Eocene Thermal Maximum (PETM), brought about dramatic change in the existing flora and fauna (Keller et al. 2018).

It is proposed that the massive release of greenhouse gases trapped in the deep ocean led to this drastic global warming, but the exact reason is still a topic of debate.

Methane released from the decay of dead microbes falling to the deep ocean floor gets trapped in a cage-like structure of water molecules in the cold, dark, high-pressure conditions and forms clathrates. These clathrates serve as the most massive methane sink, but they can melt if the sea bed temperature rises beyond a certain point and release methane gas. By the end of the Paleocene, deep-sea temperatures had grown enough to cause the melting of clathrates, releasing billions of tons of methane into the atmosphere leading to PETM.

Other researchers strongly propose the volcanism-associated release of CO<sub>2</sub> from the North Atlantic Igneous Province as the primary driver of PETM (Gutjahr et al. 2017).

The thermal maximum resulted in extinctions on both land and water. Except for the extinction of deep-sea calcareous benthic foraminifera, the PETM is considered a migration and origination event that kick-started various short- and long-term evolutions (Speijer et al. 2012).

#### Eocene Fauna

The Early Eocene saw a dramatic increase in mammals' abundance and diversity with the gradual decline of older primitive forms. Warming up

of the northern hemisphere facilitated the migration of these new mammalian orders toward higher latitudes. They were only about 60% of their Paleocene counterparts' size, suggesting that smaller body size would have helped them better manage the Eocene heat. The earliest forms of the modern mammalian orders that appeared during the Early Eocene weighed less than 10 Kg. These included the bats, artiodactyls (even toed ungulates), perissodactyls (odd toed ungulates), proboscideans (elephant-like animals), primates, rodents, and marsupials. *Eohippus*, a fossil perissodactyl from the Early Eocene, was widespread in both North America and Europe, indicating the existence of land connections between the continents.

By the Middle Eocene, all the modern groups of horses, rhinos, and tapirs were present. They had low crowned teeth, well suited to feed on the tropical and subtropical vegetation's soft leaves and fruits. Artiodactyls also became abundant. Land connection between North America and Europe was lost by the Middle Eocene, and the isolated species followed different evolutionary paths.

Global temperatures started to fall by the Late Eocene, and seasonality became more pronounced. Many archaic groups of mammals became extinct, and only those who adapted to the changing climate survived. Forests gave way to the first open grasslands, which favored an increase in body size and led to the evolution of enormously huge perissodactyls, like *Embolotherium* and *Indricotherium*. Cursorial adaptation, like lengthening of legs, the fusion of limb and ankle bones, and reduced toe number, improved their survival rates in these grasslands.

Reptiles were represented by the enormous crocodile *Deinosuchus*, pythons, and turtles in North America.

Modern birds made their first appearance during the Eocene. Global climatic conditions of the Early Eocene favored avian diversification, and after that, the evolution rate slowed down until the Oligocene (Lindow and Dyke 2006).

#### Eocene Flora

The hot and moist Early Eocene climate favored the spread of forests throughout the earth. Warm temperate to subtropical rainforests fringed

Antarctica, and tropical rainforests stretched as far as Europe.

By the Middle Eocene, earth began to cool, which led to the drying of continental interiors and the thinning of forests. Grasses started to evolve but were confined to river banks and lake edges. This global cooling set the platform for different seasons. Consequently, deciduous trees, better adapted to the changing climate, started replacing the tropical plants.

By the Late Eocene, deciduous forests covered large parts of North America, Eurasia, and the Arctic. Simultaneously, rainforests became confined to the equatorial regions of South America, Africa, India, and Australia. Open savanna-like vegetation started to become more common, with a corresponding reduction in forests. Antarctica became much colder and was covered by vast stretches of tundra by the beginning of the Oligocene.

#### Eocene Oceans

Deoxygenation due to the warming of the oceans during PETM resulted in the massive extinction of deep-sea organisms, whereas many planktons living in the shallower seas flourished and diversified. High levels of CO<sub>2</sub> in the atmosphere led to ocean acidification, affecting organisms with calcium carbonate skeletons, and, in particular, led to the significant extinction of calcareous benthic foraminifera (Speijer et al. 2012). Cetaceans and sirenians transformed from being terrestrial to fully aquatic during the Eocene.

#### Eocene Geography

North America and Europe, which were connected through Greenland, began to drift apart, and by the Middle Eocene, the continents had lost connections. This led to the opening of the North Atlantic Ocean. During this time, the tectonic activity gave rise to mountains in the west of North America, forming lakes in their flat basins. In Europe, the Tethys shrank, and the Alps uplifted. India continued to move away from Africa and began to collide with Asia. By the Middle Eocene, the Tasmanian gateway began to form as Australia started to separate from Antarctica. South America was still connected to Antarctica.

### Eocene Climate

The PETM began at the end of the Paleocene and lasted for about 100,000 years. The global mean annual surface temperature was about 13 °C warmer than the current temperature. This phase saw high precipitation, lack of any permanent ice, and CO<sub>2</sub> concentration of approx. 1,400 parts per million volume (ppmv) (Burke et al. 2018). Global climate was homogenous with little variation from the equator to poles.

The Middle Eocene marked the end of the Cenozoic warming trend, and the earth started to cool gradually. Around 45 mya, the shallow Tasmanian gateway gave rise to the earliest Antarctic circumpolar current (ACC), causing Antarctica's thermal isolation and subsequent cooling (Bijl et al. 2013).

By the Late Eocene, the Antarctic region cooled down, transient continental ice sheets formed, and the surrounding ocean began to freeze.

The Early Eocene, referred to as the Eocene greenhouse, has been a subject of interest in recent years as a warm analog of the current earth. The anthropogenic greenhouse gas emissions can lead to an Eocene-like climate, which would mean reversing a 50 million year cooling trend in less than 200 years (Burke et al. 2018). This ultrafast rewinding of the climate clock can lead to a worst-case scenario of sixth mass extinction (Keller et al. 2018). Thus, a better understanding of the Eocene climate can help us cope with the current global warming.

### Oligocene (33.9–23.03 mya)

The third and the final epoch of the Paleogene period derives its name from two Greek words *oligos* = few and *kainos* = new, referring to the few numbers of modern animals that appeared during this epoch. This epoch serves as a transition phase between the archaic tropical Eocene and the relatively modern Miocene ecosystems. The Oligocene is formally subdivided into the Rupelian (39.9–28.1 mya) and the Chattian (28.1–23.03 mya). The Eocene-Oligocene transition (EOT) is marked by the onset of a significant cooling event that transformed a largely ice-free

“greenhouse” world into a glaciated “icehouse” world. A decline of about 1.6× of atmospheric CO<sub>2</sub> across the EOT (e.g., from 910 to 560 ppmv), accompanied with the new ocean circulation, resulted in unipolar Antarctic glaciation, which drastically lowered the mean annual temperature and set in more significant seasonality worldwide (Hutchinson et al. 2020). This seasonal fluctuation led to the extinction of many animals that depended on the warm and stable Eocene climate. As a result, the cold-blooded animals that survived did not flourish the way warm-blooded animals did. This new climate favored the rise of mammals like rodents and all modern-hoofed animals.

With continued Antarctic glaciation, more and more ocean water got locked up, causing sea levels to drop, eventually connecting Europe and Asia by the Early Oligocene. This was followed by a significant, sudden, terrestrial faunal turnover called Grande Coupure. It features the extinction of many European Eocene endemic mammals and their replacement by new Asian immigrants, primarily the artiodactyls and perissodactyls (Costa et al. 2011).

The sources for the significant oil reserves of Iraq and western Iran date back to the Oligocene.

### Oligocene Fauna

The extinction of archaic vertebrates of the Eocene Epoch gave a modern aspect to Oligocene vertebrates of the northern continents. The overall mammalian diversity was low during the Oligocene due to continued global cooling and reduced endemism. Relatively free interchange of vertebrates between the northern continents during the Early Oligocene resulted in similarities between the various vertebrate faunas. Pigs and peccaries that appeared in Europe during the Early Oligocene spread to North America by the end of this epoch. Bats also became widespread in this epoch. Many perissodactyls became extinct during the Oligocene, and the ones that survived included the rhinos, horses, tapirs, and chalicotheres, which were better adapted to a colder, drier world dominated by grasses. During this epoch, artiodactyls, which included the creodonts, camels, and early ancestors of deer

and cattle, became more common than perissodactyls. Open grasslands favored a general increase in the size of these herbivores. *Indricotherium*, the hornless rhino, from the Oligocene, was the largest land mammal ever.

Availability of plenty of food and a tropical climate near the equator allowed the evolution and diversification of early primates. Fossils of the earliest apelike *Parapeticus* and the Old World monkeys from the Oligocene are known from Egypt.

Being completely isolated during the Oligocene, South America developed a unique mammalian fauna exhibiting extreme parallelism to forms found elsewhere in the world. One such parallelism was the appearance of New World monkeys in South America. It was also home to unique toothless mammals or edentates, including the anteaters, sloths, and armadillos.

Australia stood isolated from all continents with few ancestral marsupials. In the absence of competitors and predators, they exploded in forms and numbers from herbivores and carnivores to scavengers and insectivores, occupying every possible evolutionary niche.

By the Late Oligocene, horses had undergone extensive anatomical modifications and evolved better adapted cursorial limbs.

Caprimulgiformes, the insectivorous, nocturnal, soft-plumaged birds, and the diurnal raptors such as falcons, eagles, and hawks appeared for the first time.

#### Oligocene Flora

Grasses started to expand from their water-bank habitat to open tracts. On a global scale, tropical forests became confined between 15° latitudes; subtropical forests with broad-leaved evergreen trees were restricted to the lower latitudes (35°); and temperate, broad-leaved trees became common over large regions of the northern hemisphere. Extensive lowland temperate vegetation became more common in the Arctic region.

By the mid-Oligocene, broad-leaved deciduous forests started extending toward the southern regions, previously occupied by the broad-leaved evergreen species.

The Late Oligocene was marked by the global expansion of grasslands and prairies. The northward movement of South America favored forests in the southern parts.

#### Oligocene Oceans

The cooling trend resulted in reduced diversity of marine planktons, with the foraminiferans and protists becoming very prominent. It also led to province fragmentation of the marine fauna, with the migration of organisms better suited for the cold climate toward the higher latitudes. In Western Europe, the transgression of the sea brought in new mollusks characteristic of this epoch. Baleen and toothed cetaceans appeared during this epoch, as did the charcharinid sharks. The mid-Oligocene was marked by regression in the number of marine species worldwide. By the Late Oligocene, marine mammals like seals, walruses, and sea lions appear to have evolved from bear-like or otter-like ancestors.

#### Oligocene Geography

Continents continued to drift to their current positions. As Australia moved toward the lower latitudes and Antarctica moved toward the South Pole, permanent glacial ice caps began to form. Complete separation of South America from Antarctica opened up the Drake Passage allowing the ACC to flow around Antarctica, rapidly cooling the continent.

Continuous northward pushing of the African plate into the Eurasian plate further uplifted the Alps in Europe. North America and Europe, which were connected by land during the Early Oligocene, eventually got separated.

#### Oligocene Climate

The establishment of ACC resulted in rapid global cooling at EOT, and long-term glaciation began in Antarctica. In the northern hemisphere, warm temperatures prevailed, and glaciation started only in the following epoch. This disparity in glaciation is attributed to the fact that the CO<sub>2</sub> threshold for the inception of ice sheet in the northern hemisphere was lower, implying that climate should have been much colder than in Antarctica to initiate glaciation (Hutchinson et al. 2020).

## Miocene

The Miocene, the first epoch of the Neogene period, spans from 23.03 to 5.332 mya and was named by Sir Charles Lyell. The name is derived from the Greek words *meios* = less and *kainos* = new, referring to the reduction in the appearance of modern sea vertebrates by 18% compared to that in the Pliocene. It is generally divided into the Early (23–16 mya), Middle (16–11.6 mya), and Late (11.6–5.3 mya) Miocene. It is formally subdivided into six ages, corresponding to their rock stages: the Aquitanian (23–20.4 mya), Burdigalian (20.4–16 mya), Langhian (16–13.8 mya), Serravallian (13.8–11.6 mya), Tortonian (11.6–7.2 mya), and Messinian (7.2–5.3 mya).

It was a time of warm global climates compared to the preceding Oligocene and succeeding Pliocene, but the Antarctic ice cap remained intact. This temperature rise favored an increase in the total number of mammalian species. The land-dwelling mammals of this era were essentially modern, representing half of the currently existing mammalian families.

### Miocene Fauna

The formation of polar ice caps, shifting of continents, and changing climate patterns caused sea levels to drop and inland seas to shrink, thus opening land routes between continents encouraging animal migration.

Ancestors of modern elephants and apes ventured out of Africa and settled in parts of Eurasia, eventually making their way to North America along the Bering land bridge, whereas rabbits, pigs, saber-toothed cats, and modern rhinos moved from Eurasia to Africa. In North America, horses grew considerably larger and displayed a single toe on each limb. They quickly spread to Europe and Asia, subsequently reaching Africa, where some species evolved into zebras. Surprisingly, these “invading” species did not force a large number of native species to extinction. Animals that became extinct most probably failed to adapt to the changing climate and vegetation.

The geographically isolated South America was enriched with unique animals represented by carnivorous marsupials, edentates (including

anteaters, armadillos, and sloths), litopterns (hoofed mammals like horse and camel), and toxodon (mammals with long, curved incisors). South American monkeys evolved continuously during the Miocene.

Miocene primates, particularly the apes, underwent significant evolution. Around 16 mya, Orangutans or Asian apes separated from the African ape or hominid line, and around 9 mya, chimpanzees separated from the hominid line. Primates spread to southern parts of Europe, where gibbon-like *Pliopithecus* remains were found in the Miocene rocks. Similarly, *Dryopithecus's* remains, an advanced humanlike ape, were found in Miocene rocks of Europe and Africa.

As the Miocene progressed, the earth began to cool, and the arid climate brought about the spread of coarse grasslands. This brought about the Miocene extinction around 9 mya, which wiped off many herbivores feeding on fruits, juicy ferns, and shrubby plants. Animals such as the giant camels, which could not adapt to the colder climate and coarse grassy vegetation, became extinct, whereas mammalian herbivores like equids, rhinos, and many artiodactyls adapted to more open, arid habitats, and coarser vegetation survived. Primitive deer, antelope, and giraffe appeared in Eurasia. The first dogs, bears, hyenas, and saber-toothed cats appeared during the Early Miocene in North America and spread to Asia by the Late Miocene.

Birds like ducks, herons, eagles, rails, crows, pheasants, partridges, plovers, owls, and cockatoos appeared in the Miocene. By the Late Miocene, almost all modern bird families were present, and marine birds reached their highest diversity of this epoch.

### Miocene Flora

Gradual warming accompanied by aridity during the Early Miocene led to the evolution of tough scrub plants and extensive development of grasslands like the steppe in Europe. In Australia, rainforests started to shrink and were replaced by dry forests, grasslands, and deserts. C4 grasses that could assimilate CO<sub>2</sub> and water more efficiently than the C3 grasses became ecologically

more significant (Pagani et al. 2005) and well established by the Late Miocene (6–7 mya). The expansion of these silica-rich C4 grasses brought about the extinction of those herbivorous species which lacked high-crowned teeth.

Cyclical warming and cooling resulted in the appearance of kelp forests, consisting of large brown algae, called kelp (*Macrocystis pyrifera*). These kelp forests soon became one of the most productive ecosystems and played an essential role in the evolution and sustenance of marine life, such as sea otters, fishes, and invertebrates.

By the Late Miocene, drastic cooling resulted in the further shrinking of tropical and coniferous forests. Ninety-five percent of the modern plants had made their appearance by the end of this epoch.

#### Miocene Oceans

Due to global cooling, the changing ocean current circulation patterns brought about a change in nutrient distribution patterns, affecting the productivity of different regions. Miocene oceans saw accelerated evolution among marine plankton and mollusks and biological diversity in others. Marine mammals like seals and whales flourished, and cetaceans, with over 20 genera, attained their greatest diversity during this time. Gigantic predators like the megatooth sharks and raptorial sperm whales emerged during the Miocene. By the Late Miocene, almost all the modern whales, primitive seals, and walrus appeared.

#### Miocene Geography

Except for the land connection between South and North America, most of the modern geological features were formed by Miocene's end. Continents continued moving to their current position.

The Indian plate's collision with the Asian plate caused a massive upthrust of the Asian continent, creating the Tibetan Plateau and the Himalayas. During the Middle Miocene, the African-Arabian plate union with the Eurasian plate interrupted and contracted the Tethys Sea leading to the Mediterranean Sea formation. Southern Europe became arider between 19 and 12 mya, and the Tethys Sea disappeared. By the Late Miocene (5.96–5.33 mya), repeated

isolation from the Atlantic Ocean driven by tectonic activity led to nearly complete desiccation of the Mediterranean Sea, known as the Messinian salinity crisis (Krijgsman et al. 1999).

In North America, the Sierra Nevada and Cascade mountain ranges were formed, whereas in South America, the Andes were uplifted. During the Late Miocene, the upliftment of East Africa created a rain shadow in the East, making it dry, and the tropical rain forests also shrank. Australia moved to lower latitudes and became drier.

Growth of the polar ice caps and the associated drop in sea levels during Miocene exposed Florida for the first time in Miocene.

#### Miocene Climate

The Early Miocene saw an increase in global temperature. As Miocene progressed, the earth began to cool again, and the climate became arid. As a result, mammalian diversity started falling again. The upliftment of mountains in the Americas and Asia altered the air circulation and weather patterns adding to the overall dryness.

About 14 mya, global temperatures dropped drastically and is commonly known as Middle Miocene Climate Transition (MMCT). A similar temperature drop occurred once again around 8 mya, wherein the Antarctic ice sheet attained its present-day size and thickness. Variation in the carbon cycle involving the terrestrial and deep ocean carbon reservoirs played an essential role in driving Late Miocene cooling. This global cooling culminated in ephemeral northern hemisphere glaciations between 6 and 5.5 mya (Holbourn et al. 2018).

#### Pliocene

The Pliocene, the upper epoch of the Neogene period, spans from 5.33 to 2.588 mya. Sir Charles Lyell named the Pliocene from the Greek words *pleios* = more and *kainos* = new. It means “newer” or “continuation of the recent” as this era has more fossils of still-existing species, particularly modern marine mollusks. The Pliocene was relatively cooler than the preceding Miocene. The Pliocene is subdivided into the Zanclean (5.3–3.6 mya) and the Piacenzian (3.6–2.6 mya).

### Pliocene Fauna

In North America, mastodons, gomphotheres, opossums, weasels, dogs, and fast-running hunting bears flourished. Hoofed animals like camel, deer, and horse declined. Rhinos, tapirs, and chalicotheres went extinct. Mastodons, the elephant-like animals, evolved and diversified significantly during the Pliocene.

In Eurasia, rodents, elephants, gomphotheres, stegodons, cows, and antelopes flourished. Tapirs and rhinos did reasonably well, whereas the primate distribution and horse diversity declined. Some camel species and some predators like bears, dogs, and weasels migrated to Asia from North America, while hyenas and hyraxes migrated northward from Africa.

Hoofed animals dominated Africa, where early giraffes appeared and cows and antelopes diversified. Elephant, horse, and modern rhino populations increased. Camels, dogs, bears, and weasels migrated from North America through Asia. These carnivorous immigrants joined cats and civets as African predators forcing the hyenas to adapt as scavengers. Primates continued to evolve around 5.2 mya; the first humanlike primates (hominins), the australopithecines, evolved in East Africa. They descended from apes and probably lived at the edges of forests. They were adapted to walk upright and could make tools.

Around 3.5 mya, the North and South American tectonic plates joined, which resulted in the Isthmus of Panama formation. The newly formed land connection brought about the Great American Interchange, wherein the previously isolated species migrated and intermixed. Weasels, dogs, cats, bears, and horses migrated from North America to South America. In contrast, glyptodonts (giant armadillo-like animals), giant ground sloths, smaller armadillos, opossums, and porcupines migrated to North America by the Late Pliocene. *Titanis*, a South American large phorusrhacid (flightless terror birds), which migrated to North America, flourished as the top predator.

In Australia, marsupials, the dominant mammals, included both the herbivore and carnivorous forms. First, rodents reached the island continent

only by the Pliocene, and the modern duck-billed platypus (a monotreme) appeared.

As the climate cooled, crocodiles and alligators perished in the higher latitudes. Venomous snakes diversified in parallel to the evolution of rodents and birds.

### Pliocene Flora

Colder, drier, and seasonal climate reduced tropical species worldwide. Tropical forests became restricted to a tight band around the equator. Deciduous forests proliferated, evergreen coniferous forests became established in the higher latitudes, tundra covered the frozen arctic, and grasslands spread to all continents (except Antarctica). Hardy plants such as sedges, mosses, and lichens that can tolerate a short growing season inhabited the permanent tundra encircling the North Pole. Lower latitudes were covered with grasslands, and deserts began to appear in Asia and Africa. These habitats supported less animal diversity due to limited food sources.

### Pliocene Oceans

As the Arctic ice cap formed, the climate became dry, and the cold, shallow currents increased in the North Atlantic Ocean. Sea lions, sea cows, and seals flourished in the Pliocene seas.

Formation of the Isthmus of Panama divided the surrounding waters into the Atlantic and Pacific, setting the segregated marine life on different evolutionary paths. It also severed the final remnant of the circum-equatorial current, contributing to further cooling the oceans worldwide.

The end of the Pliocene was marked by large climatic fluctuations and sea-level oscillations, which led to a major extinction among the marine megafauna (seabirds, mammals, sharks, and turtles). This extinction was three times more devastating than the rest of the Cenozoic, with the extinction of 36% of the Pliocene genera (Pimiento et al. 2017).

### Pliocene Geography

Continents continued drifting to their current position. They covered a distance of 180 km during the Pliocene and reached positions only 70 km

away from their present locations. The Indian plate's further collision deep into the Asian plate raised the Tibetan Plateau and formed the Himalayas. This geological activity continued in the succeeding epochs and is still in the process. The Mediterranean Sea, which was dried up by the Late Miocene, was reclaimed by the Atlantic Ocean during the Zanclean flood in the Early Pliocene. The Alaskan land bridge reappeared between Eurasia and North America.

By the mid-Pliocene, around 3.5 mya, an eastward shift of the Caribbean tectonic plate led to the joining of the North American and South American tectonic plates. This unison of plates formed the Isthmus of Panama that connected the two continents by land.

#### Pliocene Climate

The cooling trend that set in during the Eocene continued through the Pliocene. Based on the then prevailing climatic condition, the Pliocene can be divided into a warm Early Pliocene, the mid-Pliocene with a short-lived “warm blip,” and the Late Pliocene – a period of high-magnitude climatic fluctuations associated with the glacial/interglacial cycles (Haywood et al. 2008). During the mid-Pliocene (3.3–3 mya), the average global temperature was 2–3 °C higher, the CO<sub>2</sub> level was the same, and the global sea level was 25 m higher than that of today.

Following the emergence of the Isthmus of Panama, the formation of the Atlantic and Pacific oceans impacted the global temperatures by cutting the warm equatorial ocean current and initiating the Atlantic cooling cycle. Climates became cooler, drier, and seasonal.

By the mid-Pliocene, ephemeral Arctic ice caps were formed, and by the Late Pliocene, extensive glaciation set in over Greenland. About 2 mya, both the poles were covered with permanent ice sheets.

#### Pleistocene

The Pleistocene, the first epoch of the Quaternary period, spans from 2.588 mya to 11,700 years ago (ya). The Pleistocene derives its name from the Greek words *pleistos* = most and *kainos* = new, meaning “newest.” Sir Charles Lyell introduced

this term in 1839 to describe strata in Sicily, whose 70% molluscan fauna is still living today.

The Pleistocene can be subdivided into four ages corresponding to their rock units as the Gelasian (2.6–1.8 mya), the Calabrian (1.8 mya to 780,000 ya), the Ionian (780,000–126,000 ya), and the Tarantian (126,000–11,700 ya). The Ionian and Tarantian ages await approval by the ICS.

Pleistocene is also popularly known as the “Great Ice Age” because of the repeated glacial cycles, where cold periods of glacial were interspersed with warmer phases of interglacial.

#### Pleistocene Fauna

Changing geography due to the upliftment of mountains and plateaus, the emergence of new migration routes, and the large climatic fluctuations profoundly impacted the Pleistocene fauna and flora. Every time the glacial ice advanced, plants and animals would retreat southward in response to the tremendous stress resulting from the temperature changes, reduced rainfall, food shortage, and reduced living space. Nevertheless, the Pleistocene megafauna diversity was much greater than it is today.

Large mammals like the woolly mammoth, woolly rhinoceros, moose, reindeer, and musk ox adapted to the Arctic conditions and inhabited the periglacial areas, whereas mastodon, elephant, hippopotamus, giant beaver, bison, horse, ground sloth, and deer inhabited the temperate regions.

Pleistocene is of particular interest to humans as *Homo sapiens* evolved from early hominids during this epoch and spread to all continents. The oldest species of the genus *Homo*, *H. habilis*, probably evolved from *Australopithecus* during the Late Pliocene. *Homo habilis* appeared about 2 mya and roamed in Africa till 1.5 mya. Around 1.6 mya, *H. erectus* possibly evolved from *H. habilis* in Africa and thrived as the dominant human species in parts of the Old World for over one million years. *Homo sapiens* evolved 315,000 ya in Africa. About 250,000 ya, during the last interglaciation, *H. neanderthalensis* (Neanderthals) appeared in Europe and western Asia. Around 60,000 years ago, *H. sapiens* migrated out of Africa and

arrived in Europe 45,000–43,000 years ago. Both *H. sapiens* and *H. neanderthalensis* coexisted in Europe for about 10,000 years, after which the Neanderthals disappeared 35,000–30,000 ya. By the end of the Pleistocene, *H. sapiens* had spread to most parts of the world.

The Pleistocene ended with a major extinction of many large mammals, particularly in North America. Thirty-two genera of large mammals, including the mastodons, mammoths, giant beavers, horses, and ground sloths, vanished within roughly 2,000 years. As small mammals, reptiles, and amphibians were not much affected, it is hypothesized that the extinctions were the result of overpredation by humans or due to the abrupt changes in climate.

#### Pleistocene Flora

The Pleistocene climate was primarily dry, and the vegetation belts shifted toward lower latitudes. By the end of the Pleistocene, North America's temperate zones and central Europe were occupied by the tundra vegetation, consisting of grasses, herbs, and a few trees. South of the tundra belt was a mostly sparse pine forest, and deciduous forests could only be found along Mexico's gulf. Due to the lower sea temperatures, the weak trade winds gave rise to a continuous EL Nino like condition that resulted in open grasslands where Amazon forests stand today. Whereas, heavy precipitation in central America and coastal Colombia gave rise to tropical rainforests and great lakes in the present south-western desert states. While in other cold and dry places, deserts emerged and expanded like the Sahara desert.

#### Pleistocene Oceans

The direct influence of the ice sheets brought about drastic changes in the North Atlantic Ocean. Polar marine fauna that generally occurred north of 70°N during interglacial intervals extended south to about 45°N during glaciation.

#### Pleistocene Climate and Geography Defined by Glaciation

Continents had drifted to their present position by the Pleistocene. The natural cooling of the earth that set in at the start of the Cenozoic Era

culminated in the Ice Age consisting of a series of glacials interrupted by interglacials or warm periods. During the glacial phase, ice sheets expanded from Antarctica, Greenland, and even around high mountains along the equator. It is estimated that, at the last glacial maximum, continental glaciers reached about 40°N in North America and 50°N in Eurasia. The permafrost stretched southward to a few hundred kilometers in North America and several hundred kilometers in Eurasia.

During the last glacial maximum, roughly 30% of the land area was covered with ice, locking a large amount of water in thick continental ice sheets, dropping global sea level by 100–120 m. The exposed wide coastal areas and land bridges enabled the migration of fauna, flora, and humanity across the earth. The rapid melting of the last massive glaciers raised the sea level, displaying the present level by the Middle Holocene.

Analyses of  $^{16}\text{O}/^{18}\text{O}$  in the shells of marine microorganisms from deep-sea sediments provide a better chronological record of the Pleistocene climatic events. The shells secreted in cold waters contain more oxygen-18 isotope than those secreted in the warm waters. The marine oxygen isotope record, unlike most terrestrial records, is a continuous record that serves as a standard and can be correlated to climatic events on land (like glaciation). Based on this correlative study, the Pleistocene is known to have more than ten glacial-interglacial cycles. During the early Pleistocene, glacial cycles were shallow and frequent; in the later phases, the cycles became more intense and widely spaced with the pronounced temperature difference between the glacial and interglacial. The higher latitudes experienced far more dramatic temperature differences than near the equator.

Many theories have been proposed to explain the Quaternary glaciations, but the theory of astronomical cycles is considered the best explanation so far. Astronomical cycles, also known as the Milankovitch cycles, are determined by three parameters, namely, eccentricity (departure of the earth from its circular orbit), obliquity (tilt in the earth's axis), and precession (wobble of earth's axis). These parameters collectively determine the amount of solar radiation incident on any latitude.

These latitudinal radiation variations caused by orbital parameters and the other feedback mechanisms seem to account for the Pleistocene climate change.

The air bubbles found in the drill cores from Greenland and Antarctica show a reduction of greenhouse gasses, CO<sub>2</sub>, and methane in the mid-Pleistocene, which correlates with the reduced global temperature. Lower levels of atmospheric CO<sub>2</sub>, increased amount of dust, and increased reflection from the snow-covered earth's surface would have contributed to the feedback mechanism and together caused increased cooling (Willeit et al. 2019).

### Holocene

The Holocene, the next epoch of the Quaternary period, is an interglacial phase which began about 11,700 years ago at the end of the Weichsel glaciation (the last glacial maximum of the Pleistocene) and continues till today. It is the shortest and the most intensively studied epoch in the entire geological timescale as it contains diverse and remarkably well-preserved evidence. Sir Charles Lyell named the Holocene from the Greek words *holos* = whole/entire and *kainos* = new or modern, meaning “entirely recent.”

The Holocene has been recently subdivided into three stages: the Greenlandian or Early Holocene (11,700–8,236 year b2k, i.e., before the 2000 calendar year), the Northgrippian or Middle Holocene (8,236–4,250 year b2k), and the Meghalayan or Late Holocene (4,250 year b2k till today) (Walker et al. 2019).

As humans have greatly influenced the Holocene environment, especially the latter stage, it is sometimes referred to as the Anthropocene or the “Age of Man.” The development of complex human cultures, the origin of agriculture, and the expansion of neolithic settlers transformed the landscape and altered the environmental dynamics.

### Holocene Fauna

At the beginning of the Holocene, large animals like mastodons, mammoths, saber-toothed cats, and giant sloths became extinct. Over time, man domesticated dogs, cats, and ungulates like

cattle, horses, pigs, sheep, and camels. During the Holocene, animals did not evolve much, but their distribution pattern changed.

In the last two thousand years, many species such as moa, quagga, dodo, and great auk have become extinct due to human activities like habitat destruction, overhunting, increased interspecific competition, the introduction of exotic species, and infectious diseases. This widespread extinction of species during the modern Holocene is termed as the Holocene extinction event.

### Holocene Flora

Pollens and spores well preserved in lakes, swamps, and sea sediments provide a basis for reconstructing the paleoenvironment and estimating the local vegetation. These reconstructions show a warming and drying trend, favoring cold-tolerant water-loving plants like birch and spruce in high latitudes and altitudes. These studies also provide insights into the migration of plants in response to warming. Integrating such studies with climate model predictions will help evaluate if major tree populations can migrate rapidly enough to a suitable habitat during global climate change.

During the Early Holocene, tundra gave way to birch forests in the high latitude and midlatitude. By the Middle Holocene, they were replaced by pine, followed by the oak, beach, or mixed forest. In the midlatitudes, continental interiors, facing hot summers and cold, dry winters, saw expanding prairie or steppe. More significant moisture in the polar regions led to the disappearance of the steppe tundra.

### Holocene Geography

As a result of plate tectonics, continents have drifted to their current position by about 1 km over the entire Holocene. Through the Holocene interglacial, Greenland and Antarctica, situated at higher latitudes, have retained their glaciers. In comparison, the midlatitudinal ice sheets disappeared at a tremendous rate and increased the sea level by 35 m. With the rise of sea level and removal of the glacial load, the earth's crust responded buoyantly, resulting in progressive postglacial upliftment or crustal rebound. Places at about 40°N, previously loaded with thick

glacial ice, rose to about 180 m and are still rising. In cases where the rate of rising water level was more significant than the rate of land rise, temporary marine transgression occurred. The post-glacial rebound has resulted in the Hudson Bay formation in North America and the Baltic Sea in Scandinavia.

### Holocene Climate

Holocene climate has been relatively stable, comprising changes that were primarily regional compared to Pleistocene's global climate changes. The general climate showed a warming trend from the beginning of the Holocene to 7,000 years ago. This was followed by the Holocene climatic optimum, which ended about 5,000 years ago, with temperatures 0.5–2 °C warmer than today. This was the time when the earliest human civilization began to flourish in Africa and Asia. At this time, the Nile River in Africa was three times its present volume, and the Sahara desert was a fertile land. Then, the Holocene earth entered a period of minor glaciation that lasted until 4,000 years ago. The earth went through short cooling and warming trends over the years. From AD 1100 to 1300, the climate was slightly warmer and is known as the Little Climatic Optimum or Medieval Optimum. This was followed by the Little Ice Age, the coldest period of the Holocene, which lasted till AD 1850. During this time, a large part of the population died due to crop failure and famine in Europe.

Many researchers believe that the Holocene is an interglacial period, and the earth will return to a new phase of glaciation in another 3,000 years.

### Conclusion

The Cenozoic Era, the 66.6 million years of earth's history, holds the evolutionary secrets of all life on earth today. Stacked below the earth's crust, each layer unfolds stories about the formation of continents, mountains, climatic zones, unimaginable glaciation cycles, the evolution of the mighty *Indricotherium*, majestic woolly mammoth, and the unbeatable human race from the small nocturnal mammals.

The step-by-step evolution that has taken place over millions of years is at stake as humans are taking command of their immediate environment, affecting the greater environment culminating in irreparable and irreversible losses. Though climate changes and extinctions have been a part of the earth's story, the current changes occur in a span of a few hundred years, giving meager opportunities for life to adapt.

A better understanding of the earth's past holds the key to a better future.

## Synonyms

### Map unit

## Definiton

CentiMorgan is defined as the distance between genes on the chromosome and is used to measure the recombination frequency.

## Introduction

It is a map unit used to measure the genetic linkage, which is defined as the distance between two positions along the chromosome that results in 1% recombinant individual out of 100 progenies. The distance corresponding to this 1% recombination frequency is called centiMorgan (cM) (Lodish et al. 2004).

The term centiMorgan is given to genetic unit in honor of the great scientist Thomas Hunt Morgan.

$$100 \text{ centiMorgan} = 1 \text{ Morgan}$$

If two loci are 1 cM apart, then a crossover occurs between them at an average of 1 in 100 meiosis. Therefore, cM is a measure of the genetic or linkage distance between two loci. One map unit is equal to 1 cM and 1 cM is equal to 1% recombination. Thus, two genes that recombine with a frequency of 3.5% are said to be located 3.5 map units apart. This is not the same as physical distance, which is measured in base pairs. However, in humans, 1 cM is roughly equivalent to  $1 \times 10^6$  base pairs (bp) (Fig. 1).

## Relation to Recombination Frequency

The centiMorgan (cM) values for DNA segments are measurements of how likely the segment is to

recombine as it passes from parent to offspring. Segments with higher cM values have a greater probability of recombining in any one generation. Therefore, when you share DNA segments with larger cM values with a match, your common ancestors are likely to come from generations that are more recent (Benzamine 2005).

The frequency of crossover events expressed in centiMorgan cannot be correlated with the physical distance between the markers employed. This has been demonstrated, for example, in cereals (Heslop-harison 1991), in the tomato chromosomes, and more extensively in the chromosome 4 of *Arabidopsis* (Tangkley et al. 1992). Among the progeny of parents that are heterozygous for a number of linked genes, a genetic map that places the genes in a linear array can be constructed. The distance between loci represents the frequency of occurrence of recombination and is not equivalent to a precise physical distance. However, approximations for the value of percentage recombination and the number of base pairs of DNA have been deduced by correlating physical chromosome maps with genetic maps.

So,

$$\text{map distance} = \frac{\text{Number of recombinant offspring}}{\text{Total number of offspring}} \times 100$$

CentiMorgan length represents the percent of recombination between the genes on the chromosome. The recombination rates vary among the individuals and chromosomes. The genome wide recombination rate was studied in ten *Eucalyptus globulus* and was found as between 2.71 and 3.51 cM/Mb. Not only genome wide, the recombination rate varies across the chromosome also. The 11 chromosomes of *Eucalyptus globulus* were found to have different recombination rate ranged from 1.98 to 3.81 cM/Mb (Gion et al. 2016).

**CentiMorgan (cM), Fig. 1** Recombination frequency between genes *a* and *b* is 5% and between *b* and *c* is 8%. Genetic distance between these genes is 13 m.u. or centiMorgan (cM)

CentiMorgan length also varies across the position on the same chromosome. As it was seen in *Anopheles gambiae*, the recombination rate varies from  $>7$  cM/Mb at the telomeric end of the X chromosome to  $\sim 0.2$  cM/Mb at the centromeric end (Pombi et al. 2006). The average rate of recombination varies among the individuals also like in *Drosophila* the average rate of recombination is 1.5 cM/Mb (Nachman 2002) and in human beings, it is 1.1 cM/Mb (Kong et al. 2002).

## Conclusion

CentiMorgan (cM) is a unit to measure the distance between genes on the chromosome. It is denoted by map unit. One centiMorgan is equal to one map unit and same will be the recombination frequency. The recombination rate varies not only among the individuals but also the chromosomes.

## Central Place Foraging

Joseph L. Woodgate and Lars Chittka  
School of Biological and Chemical Sciences,  
Queen Mary University of London, London, UK

## Definition

A foraging strategy in which prey or resources are transported to a nest or other habitual base rather than being consumed in situ.

## Introduction

Many animals use one or more habitual locations as nests, shelters, or storage caches during all or part of their lives and transport resources to this central place. Examples include birds bringing food to their nests to feed their chicks, bees storing honey at their nest to feed brood and provide food during periods when no flowers are available, male terns bringing food to females during courtship, chipmunks stockpiling seed for the winter, or eastern woodrats collecting nesting materials. A central place can also function as a store of information, as in ant colonies where pheromone trails radiating from the nest encode the sum of the colony's knowledge about available food sources or honeybees which dance inside the nest to communicate the position of flowers. Humans, too, are central place foragers, transporting everything from food to fuel, building materials and even status symbols or the spoils of war to their homes, often over great distances.

## Modeling Optimal Strategies

Central place foraging theory is an offshoot of optimal foraging theory, making quantitative predictions about foraging behavior by assuming that animals attempt to optimize their net gain per unit of time or energy invested. The requirement to return to a central location imposes time and energy costs in addition to those incurred by searching for, capturing, and handling prey items. These additional costs can alter the optimal strategy, which also depends on whether animals are single-prey loaders, which catch and transport a single item at a time, or multiple-prey loaders, which can acquire many items on a single trip (Orians and Pearson 1979).

To optimize foraging performance, multiple-prey loaders ought to spend longer searching for (and collecting) food, and carry larger loads, when foraging at distant locations than at those closer to the nest. Single-prey loaders, unable to increase their load by collecting more items, are predicted to prefer larger prey items further from the nest and to accept a smaller range of prey sizes. The logic

underlying these predictions is illuminated by an analogy to human shopping: it can be worthwhile to visit a local shop to pick up a few items only. Conversely, if a shop is time-consuming to reach, it is only worthwhile if the produce is particularly good and if you stock up on everything you are likely to need for some time to come.

Choice of prey gives animals an opportunity to adjust the profitability of a trip. Foragers should be choosier and more likely to specialize on the most profitable food sources when foraging further from their central place, although the optimal prey choice strategy varies in complex ways depending on the relative profitability and abundance of different items and on the time taken to handle different types of prey (Houston 1985). Smaller or less profitable items are more likely to be harvested when the best items are rarely encountered or require time-consuming handling, as well as when the round-trip time is lower. In some species, foragers will consume small prey in the field but transport larger items to the nest.

Foragers should become less selective as costs associated with foraging increase. Within a foraging trip, animals should become progressively less choosy as time spent foraging increases. Thus, single-prey loaders may return from a long foraging trip with items less profitable than they rejected at the start of the trip (Houston and McNamara 1985).

Many animals process their food before eating it. Processing prey at the point of capture will result in lighter loads to carry back to the nest, resulting in time and energy savings. Beyond a certain distance, these savings result in a lower round-trip time, and a forager should switch from processing at the central place to the point of capture. If processing can be done in stages, progressively greater levels of processing are expected at increasing distances from the central place (Rands et al. 2000).

A further prediction is that animals should choose nesting sites at the centers of profitable foraging areas, particularly when food supplies are unpredictable. Nest-searching bumblebee queens, for example, will spend weeks searching for suitable sites and in the process may first sample foraging resources before deciding where to settle.

## Empirical Tests

Empirical tests show broad qualitative support for the major predictions of the theory. For example, animals from birds to honeybees have been found to take larger loads when foraging further from their central place. Quantitatively, however, animals' behavior often departs significantly from models' predictions. Chipmunks collecting sunflower seeds spend longer filling their cheek pouches and carry heavier loads when foraging at patches further from their nests, as predicted, but neither the actual sizes of the loads nor the function describing the relationship between travel distance and load size is accurately explained by theory (Giraldeau and Kramer 1982). Although merlins switch from processing their prey at the nest to the point of capture as the distance to the nest increases, they do so at around 1/50 of the distance predicted by a model (Rands et al. 2000), suggesting that either the model used unrealistic inputs or that other factors influence the birds' decision, such as ectoparasite removal or strategies to avoid kleptoparasitism.

## Criticisms of Central Place Foraging Models

Models of central place foraging are vulnerable to the same criticisms that have been directed at optimal foraging models in general (Pyke 1984), namely, that they do not account for constraints on the ability of natural selection to optimize any particular function; that they require unrealistic simplifications of natural situations; that they ignore environmental stochasticity; that their proponents cannot determine what "currency" foraging animals ought to optimize; and that, because very different predictions can be arrived at by varying the model parameters, they can be used to explain any empirical result and so, by explaining too much, they fail to explain anything at all.

The real world is more complex and variable than that of simplified mathematical models, and it is unlikely that natural selection could equip any organism with the optimal response to every

possible scenario. Instead, evolution is likely to favor general behavioral rules that perform well on average, in the natural environment typically faced by a given species (McNamara and Houston 2009). Two conclusions follow: perfectly optimized behavior may not occur under any specific set of conditions; and the optimal behavioral rules for a given species will depend on its biology and ecology. Understanding the needs of animals within their environment and the mechanisms by which they fulfill these needs is the key to a fuller understanding of how foraging strategies evolve.

## What to Optimize

The optimal behavior in a given situation depends on what you hope to optimize. Most models use the currency of net rate of energetic gain and zebra finches, for example, forage in ways consistent with such currency; but honeybees aim to maximize energy efficiency, the ratio of energy gained to energy spent. The choice of currency may depend on the biology of the species in question. For example, social species like ants share information on the location and quality of food sources. It can be beneficial for foragers discovering a high-quality source to cut short their foraging trip to disseminate information, raising the long-term rate of energetic return of the colony at the expense of their individual short-term profitability (Dornhaus et al. 2006). Constraints, such as the need for small birds to acquire enough energy to survive the night, may mean that under certain conditions optimizing foraging efficiency is less important than simply getting enough to eat.

## Spatial Cognition and Foraging

Many models assume an animal has perfect knowledge of the distribution of resources and how to reach them. In fact, organisms start their foraging career with no specific knowledge of their environment. This is significant because the mechanisms by which they acquire and use spatial information, along with constraints and limitations on those mechanisms, determine where and

how they forage. The need to balance learning about the environment with the exploitation of known resources is an important factor in explaining why predictions of optimal foraging behavior seldom provide a perfect fit to empirical data.

Central place foragers must learn to navigate their environment and return successfully to their starting point. They must explore in search of food and develop efficient routes to get to and from foraging patches. A variety of navigational strategies are employed by central place foragers (Collett et al. 2013). Path integration involves keeping a constantly updated memory of one's position relative to a central location and can operate independently of the features of the environment. Other strategies involve learning and recognizing environmental features and include matching a visual scene to a memorized snapshot or following an olfactory or chemical gradient. In rats, grid cells and place cells provide a neural architecture for the animal to keep track of its position in space (Moser et al. 2008).

Species from insects to primates visit multiple destinations on a single foraging trip. Multi-destination routes reveal several ways in which foraging behavior is richer than previous models have accounted for. One is that foraging decisions involve more than just determining when to leave a patch: visiting many patches in turn is efficient if no single patch is rich enough to gather a full load in a reasonable time frame and can also reduce the costs of competition. Another is that the length and geometry of an entire route are likely to be more important than simple distance from the nest in determining the optimal strategy. Bumblebees visit locations in repeatable sequences that often converge on the most efficient route (Lihoreau et al. 2012), although experiments in which they do not find an optimal route have revealed that they use heuristic strategies that lead to good results over a range of situations. In addition to multiple destinations, primates like spider monkeys also use multiple sleeping sites, allowing reduced travel distances in large home ranges while retaining the benefits of a central place.

## Conclusion

The features of the environment an animal attends to, and the navigational strategies it employs, are tailored to its habitat and lifestyle. These mechanisms determine what information is available for foraging, which will influence the optimal strategy. The animal's ability to remember and follow routes will affect which patches are best to exploit, while the mechanisms by which it finds and captures prey will influence the optimal choice of food. Such information must be integrated with central place foraging models to improve success in predicting real behavior.

**Centromere, Fig. 1** Simplified illustration of a typical centromere and arrangement of complexes around it

(microtubules) associate with centromere through kinetochore to pull apart the two sister chromatids toward the opposite sides of the cell (Fig. 2). The presence of centromere ensures that each of the daughter nuclei receives one copy of each chromosome.

## Centromere

Usha Yadav  
Radiological Physics and Advisory Division,  
Bhabha Atomic Research Centre, Mumbai, India

### Definition

Centromere is a primary constriction site in all eukaryotic chromosomes where sister chromatids are held together (Fig. 1), and it plays an essential role in proper segregation of chromosomes during cell division (O'Connor 2008).

### Introduction

Centromere serves as a site specialized for attachment of spindle fibers. The site is characterized by the presence of specific DNA repeat sequences and associated complex of kinetochore proteins. In metaphase stage of cell division, spindle fibers

### Molecular Structure of Centromere

Centromere is a functional structure not just a sequence. Therefore, at molecular level, centromeres have two counterparts: first **centromeric DNA** sequence and second assembly of special proteins around it. The DNA sequence may or may not be sufficient or even essential to form a functional centromere. **Centromeric chromatin** sequences are specialized by the presence of special variant of histone protein **H3** called **centromeric protein A (CENP-A)** or **CenH3**. The presence of **CENP-A** at the centromere is common among most of the eukaryotes and assumed to be epigenetic characteristic for facilitation of kinetochore assembly at centromere. Further, **CENP-A** mediates recruitment of other centromeric proteins. For example, humans have a complex of 17 centromeric proteins associated with centromeric chromatin throughout the cell cycle, termed as **constitutive centromere-associated**

**Centromere, Fig. 2** Representation of microtubule attachment at centromere and chromosomal segregation during cell division

**network (CCAN)** (Westhorpe and Straight 2013). The complex is essential for recruitment of kinetochore proteins during cell division. Abnormal expression of many of these proteins including CENP-A has been reported to cause centromere dysfunction. Centromere dysfunction consequently results in chromosomal instability especially formation of aneuploidy and micronuclei due to improper chromosomal segregation. These phenomena are known to be linked directly with spontaneous abortions and many cancer types.

### Diversity Among Centromeres

Based on size and distribution of centromere, chromosomes have been broadly classified in to two categories; viz., (1) **monocentrics** refer to the presence of single site for centromere and represent most of the eukaryotes (Fig. 3a), and (2) **holocentrics** denote distribution of centromere along whole length of the chromosomes (Fig. 3b). Holocentrics have been reported in multiple plants and invertebrates.

Further, there are two classes of centromeres among **monocentrics**: **point** and **regional** (Fig. 4). A **point centromere** is represented by single stretch of ~125 bp specific DNA sequence

with a single nucleosome having **CenH3**. In this case, sequence is reported to be self-sufficient and necessary for the assembly of kinetochore proteins. In contrast, regional centromere DNA sequences are broad and consist of array of short tandem repeats called **alpha satellite** or **alphoid DNA** sequence ranging from 250 to 5,000 kb. Sequence similarity among alpha satellites is in a range of ~50–70%. In rare instances, formation of centromere has been reported at sequences dissimilar to alpha satellites, viz., **neocentromeres**. Moreover, inactivation of centromere in intact **alpha satellite** sequences has also been observed (Aldrup-Macdonald and Sullivan 2014). Due to these two reasons, regional centromeres are specified on the basis of epigenetic modifications particularly the presence of array of **CENP-A** histones in place of **H3** histones, and DNA sequence is assumed to be nonessential.

**Holocentrics** are now considered to be polycentrics having large array of multiple point centromeres (Steiner and Henikoff 2014). These have also been categorized into two classes by the presence or absence of CenH3 proteins. In earlier description, **CENPA/CenH3** is shown to be essential for most of the eukaryotes; exceptionally some lineages of insects, for example, lepidopterons, have been evolved having centromeres with no **CenH3**.

**Chromosomes with Unusual Centromere: Dicentrics, Acentromerics, and Neocentromere**

**Dicentrics** have two centromeres resulted from joining of two broken chromosomes both having centromeres. In such cases, often one of the

centromere gets inactivated by unknown mechanism and resists chromosomal segregation. A dicentric forms nucleoplasmic bridge after nuclear division often leads to cell death (Fig. 5).

Acentromeric bodies also result from chromosomal damage. Since acentrics cannot be segregated properly, they get excluded during formation of nucleus consequently form micronuclei in cytoplasm (Fig. 5) and get lost in further cell divisions.

**Neocentromere** is a recent observation which refers to formation of centromere at unconventional sites at chromosomes different from alpha satellite sequence. Formation of neocentromere is observed in cells with chromosomal damage mostly on acentric fragments for their mitotic rescue. They have also been observed in cancer patients having chromosomal instability. However, this phenomenon is not well understood yet and is in recent trends of centromere research.

**Centromere, Fig. 3** Distribution of centromere in a monocentric (a) and holocentric chromosome (b)

**Shape and Morphology of Chromosomes Defined on the Basis of Location of Centromere**

Position of centromere is one of the important criteria for identification and nomenclature of a chromosome. The presence of centromere divides a chromosome into half shorter and termed as **p arm** (p stands for petit in French which means

**Centromere, Fig. 4** Categorization of centromeres

**Centromere, Fig. 5** (a) Chromosomal spread from human metaphase with monocentric, dicentric, and acentric bodies. Centromeres are hybridized with sequence-specific fluorescent probes. (b) Pictorial demonstration of a dicentric, monocentric, and acentric chromosome segregation; a monocentric chromosome segregates equally

between daughter nuclei, whereas a dicentric often is not separable due to inactivation of one centromere and results in formation of nucleoplasmic bridge. On the other hand in the absence of centromere, a chromosome gets excluded from main nucleus and forms micronucleus in cytoplasm

small), and longer part is denoted as **q arm**. Any locus/gene is identified on the basis of the arm it resides in and its distance from the centromere. There are four classes of chromosomes on the basis of centromere position (Fig. 6) (Levan et al. 2009).

1. **Metacentric chromosomes:** centromere is in the middle of the chromosome and both p and q arms look equal.
2. **Submetacentric chromosomes:** centromere is little above the center of the chromosome making p arm shorter than the q arm.

**Centromere, Fig. 6** Classification of chromosomes on the basis of centromere position metacentric  $p = q$  (a) submetacentric chromosome  $p < q$  (b) acrocentric  $p \ll q$  (c) and telocentric with no p arm visible only q arm (d)

3. **Acrocentric chromosomes:** centromere is located well above the center, and p arm is considerably smaller than the q arm.
4. **Telocentric chromosomes:** centromere is located at the tip of the chromosomes; apparently no p arm is there.

## Conclusion

Centromeres are essential for proper segregation of chromosomes. They serve as a site for kinetochore formation and microtubule attachment and hold sister chromatids together until the cell is ready for chromosomal segregation. Abnormalities in centromeric function may lead to aneuploidy, aberrated cell division, and cell death.

## Cephalization

Bruno Cozzi<sup>1</sup> and Stefan Huggenberger<sup>2</sup>

<sup>1</sup>Department of Comparative Biomedicine and Food Science, University of Padova, Legnaro PD, Italy

<sup>2</sup>Department II of Anatomy, University of Cologne, Cologne, Germany

Cephalization is an evolutionary trend to concentrate sensory and neural organs anteriorly in a head. In the field of the neurosciences, it may be defined as the progressive growth of the (cephalic) nervous system during the evolution of animal life. Each species develops characteristic aspects of brain anatomy and organization that better suit a specific evolutionary trend and environmental niche. Up to a certain point, the growth and maturation of the embryonic brain summarizes the progressive phylogenesis of the species.

Cephalization is very evident in vertebrates, and the avian and mammalian brains are especially complex architectonically. The vertebrate brain is organized differently in the diverse clades, and neural cells may form efficient aggregates with a common chemical language, either in the form of nuclei or layers, the latter possibly functionally organized in columns. In vertebrates, amphibians and reptiles have brains that fall in the range of teleost fishes. Elongated animals (e.g., snakes, salamanders, eels) have proportionally smaller brains since they have heavier bodies

in comparison to animals with a robust body structure. Birds have brains 6–10 times larger and mammals around 10 times larger than reptiles of similar body weight (Van Dongen 1998).

## From Cephalization to Encephalization

Animal psychology and comparative cognitive neuroscience require trustable methodologies for a comparative analysis of the nervous system in different taxa. Many recent works have drawn attention on the relationship between evolutionary changes in brain size and behavioral complexity. However, the easiest way to compare the brain of two species within the same clade is to consider the mass of the brain in relation to body mass. The relationship of brain size to body size was the basis of Dubois' (1897) "index of cephalization." Dubois' proposal for an equation was further developed by Jerison (1973), to obtain what was then referred to as encephalization measured as encephalization quotient (i.e., EQ). Specifically, EQ is defined as the ratio between observed and expected brain mass, that is,  $EQ = E_i/E_e$ , a parameter widely applied in comparative mammalian neuroanatomy (Boddy et al. 2012). In this equation,  $E_e = E_i/0.12P^{0.67}$ , where  $E_i$  and  $P$  are the mean weight of the brain and body, respectively. The EQ value indicates, thus, whether a species possesses a brain larger ( $EQ > 1$ ), equal ( $EQ = 1$ ), or smaller ( $EQ < 1$ ) than expected for its body mass. Alternatives to the value of the exponent or to the equation originally indicated by Jerison (1973) have been proposed by several authors (Grabowski et al. 2016).

Encephalization occurs when the actual brain size (positively) diverges from the expected brain size for a species of a given mass. The difference from the expected value is used as predictor of an animal's adaptive capabilities.

The comparison of brains in different vertebrate clades such as anurans and birds are further limited by the fact that each group had its own and very long evolutionary history formed by unique adaptations. A comparison is the more complicated if animals do not have the same brain bauplan, i.e., if brains are constructed by different

structural principles, such as, e.g., the insect brain and the cephalopod brain.

Focusing on mammals, a great attention has been dedicated to inter- and intra-order comparisons among different species, using almost constantly wild specimens as a paradigm. It has been hypothesized that brain expansion in mammals is evolutionary associated, among other parameters, to sociality (Shultz and Dunbar 2010).

## Brain Size and EQ in Mammals

Evolutionary pressure can alter the brain/body size ratio in at least two ways. It could directly affect brain size or alternatively be a consequence of increase or decrease of the body size. The role of a greater or lesser magnitude of the brain is still a topic widely debated. The brain is one of the organs requiring the most energy (preceded only by the heart) and the cost of its operation is about 8–10 times higher per mass unit than that of skeletal muscles. Evolution is an "economical process" and does not enlarge an organ from which the body cannot derive a real benefit. In mammals, the increase in size is due predominantly to the enlargement of the forebrain and neocortex, leading to an increase of the primary areas (receiving thalamic afferents: motor area, visual, auditory, somatosensory) as well as secondary ones (higher mental functions). Progressive specialization and diversification in the mammalian brain arises precisely from the differential development of these areas.

Studies on brain size generally group species of different orders and apply indexes to assess the evolutionary position of each group. If we accept that brain and body size grow allometrically in vertebrates (Shultz and Dunbar 2010), we should also consider that mammals show specific evolutionary trends. In general, mammals at the top of the food network (high trophic levels) may have an absolutely large brain (e.g., the large whales) or a high EQ (e.g., primates and dolphins; Steinhausen et al. 2016). Within some (but not all) mammalian taxa, there seems to be a strong evidence for specific macroevolutionary increase in brain size, possibly explained by the social

brain hypothesis that links changes in sociality and relative brain size (Dunbar and Shultz 2007).

The mammalian species that have EQ >1 include apes and some cetacean species, mostly small-sized dolphins (Fig. 1). Elephants, killer whales, and female sperm whales are the only large mammals (weighing far more than 1 ton) with an EQ >1. It is common knowledge that sperm whales (SW; *Physeter macrocephalus*) and killer whales (KW; *Orcinus orca*) possess the heaviest brains on the planet (SW: 9.20 kg, KW: 9.30 kg) but the enormous body mass of SW prompts a relatively low EQ value (EQ <1) (for details see Cozzi et al. 2016). Other large bodied mammals like Perissodactyla (e.g., horses and rhinos) and terrestrial Cetartiodactyla (e.g., hippos, giraffes, and several even-toed mammals) fall in the group of the below-the-expected EQ (EQ <1).

Evidence shows that larger EQs or relative brain size endow species with improved cognitive abilities and behavioral flexibility, such as the ability to respond successfully to novel environments or to alternate between feeding strategies (Shultz and Dunbar 2010). These findings seem to agree with the fact that humans, dolphins, and chimpanzees have the largest known EQs. The EQ is not per se a sign of intelligence; however, a EQ <1 possibly suggests certain limitations to cognitive capabilities (e.g., self-recognition, use of tools) or to the ability to build complex social interactions with fellows of the same and other species.

It is also possible that larger animals have the tendency to minimize expensive neural tissue unless a specific function played by a certain nucleus or area is fundamental for survival and thriving. The overall value of the EQ and cortex analyses as predictors of cognitive capacities is doubtful, at least in primates, for which absolute brain size results a better prognostic factor. Furthermore, the relationship between EQ and body mass in unfavorable for the largest species within each group. The importance of interspecies variations should also be emphasized: a discrete number of horses have an EQ in the range of the cat, elephant, and close to the inferior limits of primates (Cozzi et al. 2014). Furthermore, analysis of “individual” carnivores (i.e., musteloids, bears, small felidae), whose life habits are quite solitary, but endowed with a relatively large EQ, contradicts the social hypothesis of brain development.

Within a complex and largely unexplained tendency to augment brain mass, the intense gyrification of some mammalian species (i.e., large herbivores, *Delphinidae*) suggests the presence of evolutionary factors promoting selective development of the telencephalon and adaptive shaping of the cortical columns. Based on the general concept that an increase in size of a given brain region must (or should) provide some amelioration in function, and given the limits of the behavioral complexity explanation, one must wonder why Perissodactyla and Cetartiodactyla (including marine species) developed such a cortex. Current hypothesis for the

**Cephalization,**  
**Fig. 1** Ranges of EQs in selected mammalian orders. Data from Steinhausen et al. (2016)

intensive gyrencephaly include analogies between hoofed animals and cetaceans, based on gyrification, cortical thickness, and reduction (or absence) of cortical layer-4. However not all the factors evoked to explain cortical growth may apply to all species, predominantly those that consider sociality. Apparently, the cortex of large herbivores is structurally oriented to process sensory inputs and respond with immediate motor strategies. Is it thus possible that the control of complex quadrupedal locomotion requires a larger cortical mantle but not a larger brain? However, attempts to correlate complex behaviors with brain structure or size are problematic. So, the differences in the EQ between, i.e., small-toothed cetaceans and *Bos taurus* (and like terrestrial Cetartiodactyla) are possibly related to evolutionary adaptation to different environments, feeding strategies, and consequent sensorial specialization.

## Conclusion

It is widely believed that the nervous system underwent a progressive increase in size over the course of evolution with the consequence, more or less explicit, that at each increase of magnitude corresponds to an increase in function. Learning skills, foraging strategies, or habitat management capabilities have been variously linked with this aspect, and sometimes considered the primary cause. To date, the most likely hypothesis for mammals remains the social brain (SBH, social brain hypothesis) developed in primates (Dunbar and Shultz 2007), but applicable also to various degrees to carnivores and terrestrial Cetartiodactyla. It is based on the principle that complex social groups, such as those of primates, or gregarious animals as can be ungulates, develop relational dynamics that often require the ability to manage individual conflicts and the need to remain in the group, thus the need to cope with huge computational demand, contributing to the progressive increase of brain size within a given systematic group (Shultz and Dunbar 2010).

### Definition

Cephalopods are a class of marine mollusks that are soft-bodied and contain a decentralized nervous system. Through these and other unique physiological adaptations, cephalopods have acquired a complex behavioral set unseen in other invertebrates (Mather and Kuba 2013).

### Introduction

When discussing complex nonhuman cognition, the species examined are typically mammals, corvids, or even sometimes fish. It is unusual to think of invertebrates as having intelligence comparable to these animals, but there are a few that might – coleoid cephalopods. Since ancient Greek and Roman times, philosophers have marveled at the apparent intelligence of cephalopods, and that fascination has continued well into today and for good reason. Coleoid cephalopods are often

regarded as the most intelligent and cognitively complex group of invertebrates (Schnell et al. 2021). Coleoid cephalopods (henceforth cephalopods) are part of the class Cephalopoda in the phylum Mollusca that includes species of octopus, squid, and cuttlefish. These animals have shown evidence of being able to solve intricate puzzles, change their appearance and behavior to blend in with their environment, and use tools, and they are also capable of performing similarly to humans on several cognitive tasks (Mather and Kuba 2013). The unique physiology of cephalopods provides evidence for the theory that intelligence has evolved separately, but in a similar capacity, multiple times in very different species (Schnell et al. 2021). Cephalopods have a unique ability to edit their own RNA to change their neural gene expression. This allows cephalopods to change their neural proteins, which may explain their unique nervous systems and behavioral diversity; however, it may have also stunted genome evolution that is typical in other animals (Liscovitch-Brauer et al. 2017). Each cephalopod species has its own particular adaptations that allow them to perceive and react to their environment in a way that best suits their environment. Cephalopods inhabit almost every marine environment on the planet from shallow reefs to the depths of underwater trenches. This variety of environments has required each species of cephalopod to develop highly specialized physical and behavioral adaptations. The adaptations of cephalopods have allowed them to exhibit a diverse behavioral repertoire and to perform abilities not seen in other invertebrates.

### Chromatophores and Camouflage

Cephalopods also have specialized small organs in their skin called chromatophores. Cephalopod chromatophores can be contracted and relaxed by the neuromuscular system of the cephalopod. This allows cephalopods to expose or hide pigmentation in their skin, effectively changing the individual's coloration. Cephalopods also have the capability to change their skin texture and appearance at will, giving them extreme camouflage

capabilities (Messenger 2001). They may replicate the appearance of a rock, coral, or some seaweed to avoid predation or being detected by potential prey, and they can change their entire physical appearance in a matter of seconds (Hanlon and McManus 2020). Along with changes in coloration and skin texture, some cephalopods are able to replicate the behaviors of other animals in order to hide from others. A prime example of this can be seen in the mimic octopus's (*Thaumoctopus mimicus*) ability to replicate the appearance and behaviors of other animals that share their environment. The mimic octopus can assume the general shape and movements of multiple animals including a banded sea snake (Gómez-Moreno 2019), a lionfish, and a flounder (Norman et al. 2001). They imitate these animals only in specific scenarios; for example, the form of a sea snake is only taken up when encountering the very territorial and aggressive damselfish. This ability to alter their physical appearance is not solely used to avoid predators. For example, male mourning cuttlefish (*Sepia plangon*) change their appearance to deceive sexual competitors. Large males typically guard multiple females during mating events to give themselves as many mating opportunities as possible. Rather than trying to challenge the larger males to gain access to females, smaller males will replicate female patterns to get past competitors and mate with females undetected. The small males may even retain the half of its body that is facing the large male in female patterns while presenting as male on the half facing the female so that she will mate with him (Brown et al. 2012). Cephalopods' ability to change their physical appearance is an impressive feat for hiding in plain sight, but it can also help them stand out as well. Most cephalopods will change their appearance to blend in with its environment. Sometimes when flamboyant cuttlefish (*Metasepia pfefferi*) are attacked by a predator, utilizing its typical tactic of blending in with its surroundings, they flash a bright display of colors across their body. While it is still not known for sure why this happens, it appears to startle the predator long enough for the cuttlefish to get away (Hanlon and McManus 2020). Cephalopods' ability to

change their appearance effectively and rapidly has helped them survive without any exterior protection for millennia.

## Extraordinary Eyes

Cephalopods also have a complex visual system that allows them to see polarized light and find contrasts easily, which aids in hunting prey as well as identifying how best to camouflage (Hanlon et al. 2009). Cephalopods also have unique eye morphology that can improve their sight. For example, have a "w" shaped pupil that helps aids in horizontal vision (Mäthger et al. 2013). This high level of visual acuity is useful for identifying threats, as well as conspecifics in their environment. Their vision is so advanced; octopuses can even perceive and remember individual human faces (Anderson et al. 2010). Giant Pacific octopuses (*Enteroctopus dofleini*) were tested to see if they could discriminate two unfamiliar novel humans. One human would feed the octopus during each interaction over a 2-week learning period; the other human would touch the octopus with a bristled stick. Then the octopuses' physical reactions to these humans were recorded. They found that octopuses tended to point their funnels and water jets away from the human that fed them, which provided evidence of familiarity with that person. Alternatively, the octopuses would point their funnels and jets directly at the person who touched them with the bristle stick, showing that they recognized the individual and remembered how they were not comfortable with them based on their previous encounters (Anderson et al. 2010). Another anecdotal piece of evidence can be seen from the popular documentary *My Octopus Teacher*, in which the subject of the film, Craig Foster, develops what he considers a mutual learning relationship with a singular wild common octopus (Ehrlich and Reed 2020).

## Investigative Arms and Minds

Cephalopods have a nervous system unlike that of most other cognitively complex animals. Well

studied in octopuses, these animals typically have a decentralized nervous system that extends into each of their arms and allows their appendages to react to stimuli seemingly independent of the animal's conscious awareness. Cephalopods also have armlike appendages that are lined with hundreds of individual suckers. These suckers do more than just help the cephalopods grip on to objects or prey; they are actually lined with multiple chemoreceptors that allow them to essentially taste and smell through the suckers. The suckers can also move and grip independently of one another for improved flexibility and multitasking (Mather and Kuba 2013). Cephalopods will often use their independent arms and hundreds of suckers to help them investigate and manipulate objects in their environment for their own benefit (Mather and Kuba 2013). Exploration of their environment or novel objects can lead to play behaviors in cephalopods. Play or manipulation of an object without a clear goal is often viewed as an adaptive behavior in juvenile mammals because it allows them to learn how to do necessary and potentially hazardous tasks without any real danger (Kuba et al. 2006). For example, after an exploration period, giant Pacific octopuses shoot a water jet at a novel object to move it around with seemingly no real function (Mather and Anderson 1999). Outside influences such as predation and food availability are often believed to inhibit play behaviors in animals, which are viewed as superfluous, because they redirect the animal's attention to behaviors essential to survival. However, further research found that, regardless of how much food an octopus was presented with, several individuals still engaged in play behaviors, suggesting that play is somehow adaptive to cephalopods (Kuba et al. 2006). Perhaps one of the ways play is adaptive is transitioning from exploring and playing with objects to using them as tools.

One of the most documented cases of tool use in octopuses can be seen in the veined octopus (*Amphioctopus marginatus*), often referred to as "the coconut octopus." The veined octopus earned this nickname because of its tool-use behavior of carrying hard objects to defend itself from potential predators. The octopus will find some form of

discarded object and carry it around with them and hide inside of it when a predator approaches them. The octopuses will continue to carry these objects with them, most likely to prevent attacks at another time (Finn et al. 2009). Another example of tool use in octopus was observed by documentary filmmakers of the special *Blue Planet II*. They caught a common octopus (*Octopus vulgaris*) gripping multiple shells in its suckers and surrounding their mantle with the shells in an attempt to either camouflage with the substrate or act as an outer defense layer to prevent predation from sharks (Jeffs and Brownlow 2017). It has also been shown that other octopus species, including juvenile common octopuses, will use objects in their environment to create or modify a defensive den to live in and to protect themselves from predators (Mather 1994). Squids and cuttlefish have not shown evidence of being able to utilize outside objects for protection or hunting. However, some species including bobtail squids (*Sepietta* sp.) and the common cuttlefish (*Sepia officinalis*) have been shown to use their water jets to shoot pressurized water at substrate to help them dig burrows. The cephalopod will then sit in that hole and cover themselves in sand to avoid predation (Mann and Patterson 2013).

## Higher-Level Functioning

The octopus does have a central nervous system housed in their mantle that contains both the common mollusca ganglia as well as lobes that execute higher-order functioning. This system can aid in cognitive tasks such as learning and memory in cephalopods (Carls-Diamante 2019). Most cephalopods have shown evidence of having long-term memory. Both octopuses and cuttlefish have demonstrated evidence for short-term memory as well (Schnell et al. 2021). One species of squid (*Euprymna scolopes*) has shown that an individual can learn that a prey item is inaccessible after one failed attempt at accessing it and then retain that knowledge for up to 12 days after the training period (Zepeda et al. 2017). Cuttlefish have shown evidence that on top of possessing both short- and long-term memory, they may also

have episodic memory. Researchers argue that cuttlefish foraging behavior shows evidence of episodic memory. Cuttlefish appear to keep track of what they have eaten, where, and how long ago, all aspects that are required of an episodic memory. Cuttlefish will remember the location where they hunted, what the food source was, and approximately how long it has been since they hunted there before the food source would replenish (Jozet-Alvez et al. 2013). Cuttlefish will change their foraging strategy and where they choose to hunt based on the availability of preferred food items (Billard et al. 2020). Cuttlefish exhibit high levels of self-control. Cuttlefish were trained on a delay-maintenance task, meaning that if they were presented with a small reward, but did not take it right away, they would be offered a larger reward. After their training trials, cuttlefish were capable of waiting for up to 2 min for a larger reward (Schnell et al. 2021). The common octopus has shown evidence of social learning. One study found that untrained common octopuses learned to correctly select a target object much faster when they were able to observe a trained conspecific complete the task first versus those who had to be trained via traditional conditioning techniques (Fiorito and Scotto 1992). This is an interesting finding because the common octopus, like most octopus species, is typically a solitary creature meaning that natural occurrences of observational learning would be unlikely and, therefore, not a very adaptive skill to have. However, cuttlefish that often live within closer proximity to others of its kind, unlike octopuses, do not seem to show any evidence of being able to socially learn (Huang and Chiao 2013). Octopuses seem to be able to take previous knowledge and apply it in novel scenarios. Common octopuses were trained to manipulate a container to retrieve a food reward. Then in later trials, the situation was changed, from how the container was placed, how they could gain access to it, and barriers placed between them and the container. Despite each of these situations being different in some way, the octopuses were still able to take their previous knowledge on how to manipulate the container and successfully retrieve their reward (Richter et al., Richter et al. 2016).

## Conclusions

The unparalleled physiology of cephalopods has given them behavioral adaptations unseen in most of the animal kingdom. The lack of hard parts in their bodies, accompanied by specialized pigmentation organs, allows them to fit in or stand out in any environment (Messenger 2001). Their extraordinary visual and nervous systems perceive, explore, and manipulate aspects of their environment to their greatest advantage, even without full conscious awareness (Mather and Kuba 2013). They learn and remember how to solve tasks quickly and efficiently (Richter et al. 2016). Cephalopod cognition is very advanced, and there is still so much to uncover in the minds of these creatures.

## Cephalopod Communication

Jennifer A. Mather

University of Lethbridge, Lethbridge, AB,  
Canada

## Introduction

All living organisms need information, but they send, receive, and deal with it in many different ways. Not all information received by animals is the result of communication, as some is accessed directly from the environment, and communication consists of signals initiated from and received

by organisms. Bradbury and Vehrencamp (2011) define such signals as “produced by a sender and monitored by a receiver, to the average net benefit of both parties” (page 4). The benefit must be average, as it is not always obvious what the receiver gains, and that communication actually has taken place may also be difficult to prove. It should result in a change in the behavior of the receiver, but this will not be seen if the communication is designed to deceive, as in camouflage. Deception is communication – passage of information – though with a different goal. Communication can also be directed to several classes of receivers: conspecifics, potential predators, and possible prey. Bradbury and Vehrencamp (2011) point out that communication must also be dependent on the delivery capacity of the communicator, the sensory abilities of the receiver, and the environmental context in which the information passes. The cephalopods’ environment and physiology are different from mammals’, and their behavior is little known. Thus, this account is based only on the species and situations that have been accessed.

There are approximately 800 species of coleoid cephalopods, an offshoot of the ancient and now extinct belemnoids. They have lost the protective molluscan shell and developed high-performance physiology, a centralized brain and acute senses, probably as a result of competition with the bony fishes. A few shelled nautiloid species have completely different physiology and sensory capacities and will not be considered here (see Darmaillacq et al. 2014). Since fishes dominate the oceans, much of the cephalopods’ communication must have been shaped by pressure from this group, and thus matched to their receiver characteristics. As a medium for communication, water is excellent for transmission of mechanical deformation signals due to its high density. It is also a good medium for passage of chemical signals. As water filters out light, visual information is only available in the surface waters, but for many species bioluminescent signaling is common in the depths. Unfortunately, the depths are inhospitable to air breathers such as humans, and the modern laboratory to its inhabitants, and so little research has been carried out on the

communication of deep sea cephalopods. However, observations from the deep-diving ROVs showed surprising display of repertoires, especially of squid (see Darmaillacq et al. 2014).

## Visual Communication

Communication must depend on the sensory structures, and coleoid cephalopods have a lens-type eye (Gleadall and Shashar 2004) that is an excellent example of convergent evolution with that of the mammals and birds. However, they have only a single photopigment with a peak at 492 nm and are thus functionally color blind, although they can discriminate the plane of polarization of light, an ability which may be used in intraspecific communication. There is only a 10 degree frontal overlap of the field of view of the two eyes, so cephalopods are functionally monocular, with information passing initially contralaterally to the brain. Octopuses can discriminate visual shapes based on several characteristics, including vertical and horizontal extent, size, edge/area ratio, and shape, and can learn to attend to salient cues (Wells 1978). The skin display system (Messenger 2001), particularly of cuttlefish and squid, is the most important output system for intra- and interspecific communication, though the bases of its control and feedback about its operation are complex and not well known. Chemicals may also be very important for communication, especially in octopuses and cuttlefish, but they are poorly studied. Although cephalopods have sophisticated mechanoreceptive capacity, its use in communication has never been studied.

The skin display system of the coleoids is their primary means of visual communication. A surface layer of chromatophores consisting of elastic sacs containing yellow, red, and black pigment and muscles with direct neural control to expand them (Packard 1995) is the main unit for signaling. When these sacs are contracted, a deeper layer of leucophores that reflect ambient wavelengths of light and iridophores that reflect in the blue range is visible and changes the animals’ appearance. Formation of skin displays is assisted

by the muscles in the skin that modify its texture and by actions and postures that change appearance. One nerve projects to several chromatophores, and several nerves may project to each chromatophore, producing graded output in terms of both intensity and area (Messenger 2001), which allows extensive signal modulation (Mather 2016). Polyphenism, or ability to change appearance, can allow cephalopods to match general background (Darmaillacq et al. 2014) or specific items (masquerade) including seaweed and animals such as flounders and hermit crabs. As predators learn the general appearance of prey, changes in skin pattern over seconds will mean the animal's appearance fails to match the predator's "search image," so it avoids detection. Skin appearance is apparently controlled at three levels (Mather and Alupay 2016). One is a reflexive adjustment of chromatophore diameter due to illumination level, which is not a communication. A second is programmed adjustment to background-matching appearance (Darmaillacq et al. 2014) by several techniques (see Fig. 1 for a catalogue of repertoires), so as not to be noticed. A third level is specific signals to prey, predators, or conspecifics, modified by learning of receiver characteristic and situations.

A first step to understanding the communicative function of cephalopod visual displays would be to make a catalogue of species-typical repertoires. Skin displays are hierarchically organized; many units make up a component, and many components combine to a whole-body pattern (Messenger 2001), of which there may be around 12–15; see also Mather and Alupay (2016). Just over 20 fairly complete catalogues appear in the literature (see Fig. 1), and many squid pattern repertoires are known mainly by sexual displays occurring only at the end of the lifespan. Combinations of components have only been assessed for *Octopus insularis* and variation and context in specific displays quantified for *Sepioteuthis sepioidea* (Mather 2016). Some details of pattern development are mentioned for *Octopus vulgaris* (Packard and Sanders 1971) and *Sepia officinalis* cuttlefish (Hanlon and Messenger 1988). Thorough investigation of the communicative function of these displays has only been conducted for the

camouflage patterns of *S. officinalis* and the male sexual displays of the loliginid squid.

## Skin Displays for Camouflage

Skin displays can produce camouflage in several different ways, including but not limited to disruptive coloration, background matching, and distraction (Darmaillacq et al. 2014), so that the animal is either not detected or not recognized as an animal. Researchers began the investigation of simple background matching and found that cuttlefish produced three display patterns – uniform, mottle, and disruptive – when placed on background with different visual pattern characteristics. An animal has to perceive a visual image in order to produce a match to it. The researchers assumed that, like humans, cuttlefish processed a visual scene by spatial frequency assessment, breaking down illumination changes by Fourier analysis of spatial phase and frequency, i.e., measuring unit size and contrast. They used Marr's (1982) proposal that bottom-up analysis of an image begins with local feature detection and then elaboration of these features into a "2 ½ dimensional" representation of the scene (see Darmaillacq et al. 2014). Such an analysis fits well with the hierarchical component combination theory of skin displays (Hanlon and Messenger 1988) and allowed them to see how local background features could stimulate the production of one or another of these three background matches. Chiao et al. (2015) have a good review of the work.

First with manual analysis and then using Fourier transformations, they discovered that component size of checkerboard stimuli was a major driver of camouflage pattern choice, as animals placed on backgrounds with small components produced uniform, larger ones mottle and largest the large-unit disruptive pattern. Mean background intensity was secondarily important, as darker substrates tended to evoke a larger disruptive response. Pattern production was also strongly evoked by abrupt changes in intensity (edges), although a natural environment rarely has complete edges. Cuttlefish were as likely to

**Cephalopod Communication, Fig. 1** Catalogues of the display repertoire of cephalopods

respond with disruptive patterns to fragments of edges, even as little as a quarter of a circle, as they were to complete figures, and appeared able to complete edges fragmented by gaps, an operation also present in humans and used in the Gestalt approach to visual pattern analysis. Researchers checked aspects of background matching, including that cuttlefish used simple luminance contrasts, reinforcing that they could not perceive

color. Camouflage was assisted by position of the arms, as cuttlefish lined up with vertical orientation of arms to match vertical stripes on a wall behind them.

Both background and skin patterns are more complex than the assessment of simple low-level features and the production of three simple skin patterns. Principal components analyses (PCA) of the 42 chromatic, textural, and postural

components separated these smaller units into combinations (Darmaillacq et al. 2014) and gave a more sophisticated test of matching. Additionally, cuttlefish were tested with local versus global luminance changes, where patches of “objects” with high internal contrast were placed on a uniform background, resulting in more disruptive components of displays, suggesting perceptual grouping. Even a few white elements on a dark background evoked a disruptive pattern, and only high-frequency information was necessary to stimulate the production of disruptive with white discs, whereas both high and low frequency were needed for black ones. The perceptual processing system was clearly much more sophisticated than the original three-pattern model suggested, though based on low-level component analyses. We know little about how feature integration and pattern production are carried on, though. Stimulation of the optic lobes of the brain produced whole skin patterns, not specific to particular regions of these lobes (Liu and Chiao 2017), suggesting that this is the location of such integration.

Ironically, few experiments have given cuttlefish choices of substrates on which to camouflage. *S. apama* giant cuttlefish actively chose substrates with a high variance in intensity when producing camouflage, while males producing agonistic display stripes chose simpler ones, presumably to more clearly convey a message rather than blend into the background. With several actual substrates, *S. officinalis* cuttlefish chose not by visual characteristics but by “looseness,” so that they could bury into the surface. Given substrates of different unit sizes, juvenile cuttlefish chose small ones (Mather 1986); they would camouflage on larger stones but bury into smaller-grained sand. If the first choice of response to substrate is burial, it is astonishing that the sensitivity and repertoire size of the response of visual cue matching are so sophisticated. No ethological observations of *S. officinalis* in its natural environment have been conducted, so the ecological reasons for these abilities and choices have not been traced.

Sophisticated analysis of visual information was also used in a different predator threat situation, when a predator had detected a cuttlefish.

Escalated threat brought a sequence of cephalopod responses (see Darmaillacq et al. 2014). Cuttlefish (Langridge 2009) responded with a dorsal surface eyespot deimatic display to a fish approach, and these spots could be expressed unilaterally. Cuttlefish deimatic responses consist of four components – light background, eye spots, black rings around the eyes, and black lines along the fins. These displays presumably startled a potential predator and inferred a large animal by the placement of the dark “eyes.” When approached by sea bass, cuttlefish commonly showed eye ring and spots, which appeared to disrupt the fish’s attack sequence (Staudinger et al. 2013), and then the cuttlefish fled. Cuttlefish learned the appropriate species to which to employ deimatic, as they did not show the display to crab or dogfish predators who use chemical rather than visual cues to locate prey. Similarly, they did not address large sea bass with a deimatic display, only juvenile ones (Langridge 2009). Large predators elicited a camouflage flamboyant display or flight and smaller ones the eyespot display, so assessment of the predator risk preceded choice of actions. This evaluation was partly due to visual assessment of stimulus characteristics (Cartron et al. 2013). A looming stimulus was projected onto one side of a container in four shapes: circle star, rectangle, lozenge, and fish. More and more intense deimatic responses were made to the star and the approaching-fish shapes than to the other three stimuli. In the natural environment, squid used different approach characteristics (size, speed, distance) to choose appropriate avoidance behavior from different fish species (Mather 2010).

Thus, the sophisticated analysis of visual stimuli is both domain general and flexible.

## Male Sexual Displays and Game Theory

In a totally different area of research, male squid displays have been evaluated in the context of game theory (Smith 1974) and sexual selection. In sexual encounters, male individuals “ought to” display their resource-holding potential in contests between one another, either tournaments

with physical contact or displays without it. Generally the resource-holding potential will be accurately displayed but not always, and winners of such contests gain access to resources, in this case a female – but again not always. Males can adopt alternate access strategies to females, either ontogenetically changing with maturity or quickly changing dependent on the particular rival. Researchers in this area have a tendency to use value-laden words, such as sneaker, owner, deception, and cheat for these strategies, as if there was a correct or more appropriate set of actions. Semelparous cuttlefish of the genus *Sepia* (see Hall and Hanlon 2002) and squid of the family Loliginidae (*Loligo*, *Doryteuthis*, and *Sepioteuthis*) tended to aggregate for reproduction during the end of their lifespan at specific sites where females laid eggs. Males were attracted to these “mops” of eggs and were stimulated by both chemical and visual cues from them. *S. sepioidea* did not aggregate but maintained long-duration groupings (Mather 2016), which may account for its more nuanced displays and interactions. Within these aggregations, animals carried on scramble competition, with considerable female choice and a variety of display and contest behaviors, and escalation that Schnell et al. (2015a)

described as mutual assessment strategies, while unfortunately disclosing little of the behaviors involved.

To gain a complete picture of the displays and other behaviors involved in sexual encounters, three components – ethogram of the display repertoire, male behaviors during contest escalation and within alternative strategies, and display repertoire of females – are necessary, and only Mather (2016) reports for all these areas. Monitoring of signals in other sensory modalities and knowledge of identity of individuals are also needed (see the next section), and a component might either not be present or just have been overlooked. Visual displays by males were a component of their agonistic interactions (Fig. 2), but every species observed except *S. sepioidea* escalated from displays to physical contact. Perhaps because they only used display contests, males of this species had spatial and intensity variation in the aggressive zebra, from minimal area of stripes on a pale brown background, aimed unilaterally to a rival (Mather 2016), to the escalating intense pale background, spread arms, and over-under position of the “formal” zebra contest. Adamo and Hanlon (1996) found that intensity of *S. officinalis* zebra displays varied spatially by

Cephalopod Communication, Fig. 2 Sexual strategies of some cuttlefish and squid

extension of the first lateral arm and also in intensity by the addition of a dark “face” component. They pointed out that the dark face is a signal of agonistic intensity and that, contrary to game theory, it appeared at the beginning of the contests. However, males attempted mating with any individual that did not display the zebra, so dark face might be a token of maleness that prevented mating attempts. The male fin base stripe of *S. sepioidea* was displayed both to females as a component of sexual displays and to males alone and might also be a sexual identifier (Mather 2016). All the known repertoires of sexual displays consist of many components, and the “meaning” of most of them has not yet been studied.

Despite this, the system has many similarities within the squid and also across to the cuttlefish (Fig. 2). Males competed and escalated these contests, and the winner was generally the larger individual (see Smith 1974). Males guarded females against rivals, though the consortship was as short as a few minutes and both males and females had multiple partnerships. In some cases, utilizing the polyphenism of the skin system, males used alternative strategies to gain matings. In several species, small males dashed in close to a female and mated with her even though a guarding male was present. In *Sepioteuthis sepioidea*, a smaller peripheral male sometimes gained a mating opportunity when a pair of large males was involved in a formal display contest, or repeatedly challenged a larger male so that he never gained the opportunity to pass a spermatophore to the consort female. Given the polyphenism of the skin system, smaller males sometimes adopted a display that was normally found in a female and gain access to a guarded female (Hall and Hanlon 2002). Sometimes the sexual pattern was expressed directionally. A male *S. sepioidea* sometimes displayed a sexual stripe pattern to the side of his consort female at the same time as showing an agonistic zebra to a rival male on the other side. Escalation of zebra pattern intensity might be the result of increase of motivation and hormonal modulation, as cuttlefish contest losers that were given an opportunity to mate with a female increased their subsequent

display intensity (Adamo and Hanlon 1996). But this choice of two different displays with contrasting motivational contexts to two receivers on either side must have cognitive capacity underpinnings.

Not as much attention has been paid to the communication of females within this system, but observers all noted that female choice controlled whether a spermatophore was accepted, and the female rejection rate could be as high as 70% of attempted matings (Hall and Hanlon 2002). Sperm deposition only occurred in *S. sepioidea* if females performed a parallel swim with males (Mather 2016). Female *S. apama* rejected males with a unilateral longitudinal white stripe display (Schnell et al. 2015b) and encouraged them with extended white arms (Hall and Hanlon 2002). Other components in the long list of display catalogues probably acted as modifiers in sexual interactions. Components of the diverse *S. sepioidea* display repertoire were suggested to be the equivalent of components of a human language. Despite the complexity of the displays of this species, the messages all appeared to be communication about the sender alone, and thus not an equivalent of language (Mather 2016). Still, there are many display components whose “meaning” has not been evaluated, and their role in communication needs to be worked out.

## Chemical Communication

As for many marine animals, cephalopods have acute chemical sensing from sensory receptor cells in several different areas – the suckers, the “lips” surrounding the mouth, and the “olfactory organ.” The olfactory organ of octopuses contains more than one receptor cell type (Polese et al. 2015), and it has been considered the location for distance chemoreception, and see Morse et al. (2017) for *Haplochlachena*, although result of testing for its function can be ambiguous. Nevertheless, cells in each olfactory organ are sensitive to several chemicals. However, not all chemical reception can be considered communication, as chemical cues are picked up about predators, prey, items in the environment such as

conspecifics' eggs, as well as conspecifics. A dictionary definition of a pheromone is a chemical that is released and subsequently causes a change in the behavior and/or physiology of conspecifics. Thus, sensory cues from eggs are not strictly pheromones, despite their designation as such, although they had a strong effect on agonistic behavior of males nearby. Testing for the effect of a water-borne chemical cue is difficult, and ideally both change in receiver behavior and physiological effect of specific chemicals on the olfactory epithelium would be carried out – but such a thorough assessment is rare for cephalopods. One general behavioral response, simplistic but probably important because of that, was arousal as judged by the ventilation rate of a stationary animal, first used systematically for different sources by Boal and Golden (1999) in cuttlefish. Ventilation rate must be used as a behavioral measure with caution because ventilation rate is a general response to stimuli as varied as food cues, a potential predator, a conspecific, and a cephalopod ink, even to water from a new source. In addition, any stimulation such as the movement to a test tank and/or introduction of a new water flow caused a change in the ventilation rate. Yet approach behavior such as a choice of arms in a Y maze might not have been an appropriate action after recognition of a chemical cue from a conspecific and was not always observed. Such an approach to the source of stimulation might be more appropriate to chemical cues from a potential food source, and chemical cues from conspecifics' ink discharge triggered escape behavior. With these caveats and a lack of general information about identity of chemicals and appropriate behaviors, there are two different areas where chemical communication has been shown to be important for cephalopods (Fig. 3).

Earlier accounts of the reproductive behavior of cuttlefish emphasized vision. Boal (2006) felt that while visual displays were important for male-female competition and courtship, female choice might be also linked to chemical signals. Females given a choice of two males to approach did not choose the larger, and they preferred males who had given fewer visual zebra displays, even after observing these agonistic interactions. They

did prefer males who had more recently mated, which made her wonder if chemical cues were involved in attraction. Ventilation rate of juvenile males increased significantly to water that had housed conspecifics, though also to many other stimuli. However, testing in a Y maze did not result in choice of the arm which had water from the tank of a conspecific. Perhaps this cautious behavior was necessary because cephalopods are cannibalistic (Ibanez and Keyl 2010), and approaching for mating could place a male in danger from his partner. Nevertheless, some octopuses were attracted to water-borne cues about conspecifics and chose an arm of the Y maze with chemical cues from them. Such approach behavior also varied across the sexes, given that male *S. officinalis* attempted to mate with any mature conspecific that did not return their zebra display. A well-controlled study of *Hapalochlaena* octopuses found that females increased ventilation rate to water with male odor, but males showed no difference in response to any chemical (Morse et al. 2017). Many more studies with closely controlled conditions are needed to sort out the stimuli and responses.

Responses to ink from a conspecific have been more consistent, even though ink is not normally thought of as a communicative stimulus. Many cephalopods released ink at predator approach, either diffusely to shield the animals from the predator's view or with mucus to make a distracting "pseudomorph" imitation of the self. Inking was accompanied by clear body appearance and escape jetting (York and Bartol 2016), another use of polyphenism. The chemicals in the ink also affected the behavior of the receiver. Derby et al. (2007) tested the aversive characteristics of the ink of nine mollusk species, three *Aplysia* sea hares and six cephalopods. All contained high levels of free amino acids which might have caused sensory disruption, and ammonium, matching the receiver sensitivity of fish and crustaceans. Ink was both a visual and a chemical defense, delaying predation but also affecting ingestion by the fish and essentially communicating unpalatability. At the same time it caused a ventilation increase and an escape response. Thus, a substance which was likely

| Species               | Sense    | Source of stimuli  | Test type                      | Result                        | Authors           |

## Cephalopod Diet

Taryn Eaton  
Oakland University, Rochester, MI, USA

## Introduction

Throughout their lives, cephalopods are ravenous predators (Budelmann 1996). Within just a few days of hatching, cephalopods begin actively seeking food and are able to successfully capture prey (Villanueva et al. 2017). Most cephalopods are generalist feeders, with the majority of cephalopod diet made up of crustaceans, fish, and molluscs (Budelmann 1996). The predatory lifestyle of cephalopods has led to the development of advanced sensory systems used in the detection of prey (Budelmann 1996; Villanueva et al. 2017), as well as a repertoire of hunting (Hanlon and Messenger 1996) and feeding behaviors (Hanlon and Messenger 1996; Mather and Scheel 2014; Villanueva et al. 2017) that have been recorded in both natural and laboratory settings. The following text will review the nutritional requirements and prey preferences of cephalopods, the sensory systems used for detecting prey, modes of hunting, and feeding behaviors utilized by

cephalopods. Gaps of knowledge will be addressed with suggestions for directions of future research.

## Nutritional Requirements and Prey Preferences

Yolk reserves are crucial for the survival of cephalopods during the first few days after hatching, fueling metabolism while hatchlings' prey-capture skills develop (Vidal et al. 2002). However, the energy contained in the yolk is rapidly depleted and hatchlings must quickly capture enough food to meet their metabolic requirements (Vidal et al. 2002). Large protein and amino acid contents are necessary for maintaining growth and fulfilling energy demands, especially in fast growing, shallow water cephalopod species (Navarro et al. 2014; Villanueva et al. 2017). Lipids and long-chain polyunsaturated fatty acids (PUFA) also play an important role in the cephalopod diet due to their inability to synthesize these nutrients (Monroig et al. 2013; Navarro et al. 2014). The elemental composition of cephalopods' natural diet suggests that copper, a key element in the respiratory function of haemocyanin (a protein which transports oxygen in the bodies of some invertebrates), is essential to many cephalopod species (Navarro et al. 2014). Sulfur is essential for the common octopus (*Octopus vulgaris*) and cuttlefish (*Sepia officinalis*) to sustain formation of muscular proteins, vestigial shell, and chitinized structures such as beaks (Navarro et al. 2014). Additionally, strontium is crucial for statolith development and, subsequently, for normal swimming and survival of newly hatched cephalopods (Navarro et al. 2014).

All cephalopods are carnivorous, and many species of cephalopod exhibit a preference for live prey, with an exception being the deep-sea species vampire squid (*Vampyroteuthis infernalis*), which feeds mainly on detritus (Villanueva et al. 2017). Crustaceans are present in nearly all cephalopod diets, allowing for the nutritional requirements outlined above (i.e., lipids and copper) to be met (Mather and Scheel 2014; Villanueva et al. 2017). In addition to crustaceans, cephalopods prey on

shrimp, fish, mollusks (including bivalves and gastropods), polychaetes, echinoderms, and hydroids (Mather and Scheel 2014; Olmos-Pérez et al. 2017). Larger cephalopod species, such as the giant Pacific octopus (*Enteroctopus dofleini*) and the Brazilian reef octopus (*Octopus insularis*) will also occasionally feed on marine birds (Anderson and Shimek 2014) and the jumbo squid (*Dosidicus gigas*) has been found to prey on skipjack tuna (*Katsuwonus pelamis*) and yellowfin tuna (*Thunnus albacares*; Olson et al. 2006). Cannibalism is common in most cephalopod species and is influenced by a number of factors including stress, population density, food availability, environmental variations, body size, and sexual dimorphism (Ibáñez and Keyl 2010).

Studies conducted on feeding behavior in cephalopods have suggested prey recognition and preferences may be both innate and/or learned depending on the species. For example, Portela et al. (2014) found that, despite being exposed to visual and chemical stimuli from shrimp 48 h before and after hatching, or being fed only shrimp 16 days after hatching, early Mexican four-eyed octopus (*Octopus maya*) still preferred crabs when given the option between crab and shrimp. However, Darmaillacq et al. (2006, 2008) found that the common cuttlefish's (*Sepia officinalis*) innate preference for shrimplike prey could be changed to a preference for crabs by visually exposing new common cuttlefish hatchlings or embryos during late stage embryonic development to crabs. This preference change was dependent on the length of time and number of crabs that were exposed (Darmaillacq et al. 2006). Both innate and learned preferences have their benefits. Innate prey preferences may aid in reducing the time spent searching for and testing alternative prey and in decreasing the risk of mistaking a deadly predator as prey (Robin et al. 2014). Being able to learn the visual characteristics of prey during late stage embryonic development and immediately after hatching allows for preferences of prey abundant in the immediate area (Robin et al. 2014). This may aid in the transition from yolk utilization to active predation, a period in which hatchlings are at risk of starvation (Robin et al. 2014).

## Detecting Prey

Cephalopods have complex sensory systems, considered the most sophisticated out of all invertebrates and comparable to the equivalent vertebrate systems (Budelman 1996). These sensory systems are used in a wide range of behaviors, including predation. Arguably, the most important sensory system for predation in cephalopods is the visual system. With the exception of *Nautilus*, cephalopods have highly developed eyes and are extremely visual animals (Cosmo and Polese 2017). Cephalopods are sensitive to polarized light, which enhances their ability to detect and recognize prey (Villanueva et al. 2017). For instance, Shashar et al. (1998) found that squid hatchlings attacked planktonic prey at a 70% greater distance under polarized illumination as opposed to depolarized illumination. Polarization vision has also been shown to aid cuttlefish in prey detection in murky waters (Carton et al. 2013).

Chemoreception also plays an important role in prey detection in cephalopods. Most coleoids (i.e., octopus, squid, and cuttlefish) are nocturnal, or live at depths where little light is present, making the ability to detect prey through chemoreception vital to their success as predators (Budelman 1996). Cephalopods use either contact (taste) or distant (smell) chemoreception to detect chemical cues (Cosmo and Polese 2017). The organs used in distant chemoreception are the rhinophores of *Nautilus*, which are located right below the eyes, and the olfactory organs of coleoids, located below and posterior to the eyes (Budelman 1996). Behavioral evidence for distant chemoreception shows that a blinded octopus will move in the direction of a scent that it perceives as a food source (Chase and Wells 1986). Additionally, cuttlefish with previous exposure to crab odor exhibit more sophisticated predation techniques on their first attacks on crab than cuttlefish that had not been previously exposed (Boal et al. 2000). The receptors used in contact chemoreception are located on the distal region of the long digital tentacles of *Nautilus* and in the lips and suckers of coleoids (Budelman 1996). In octopuses, there is an estimated 10,000 chemoreceptors per sucker, totaling 16 million cells per animal

(Budelman 1996). In cuttlefish, only 100 chemoreceptors are present in each sucker (Budelman 1996). This difference may be due to the fact that octopuses often search for food in areas they cannot see, using their arms and suckers, whereas cuttlefish and squid do not (Budelman 1996). Behavioral evidence for contact chemoreception has shown that nautiloids are still able to detect odor when one or both rhinophores are blocked but are unable to orient towards the odor source (Basil et al. 2000) and the response of blinded *octopus vulgaris* to sardine blood is unaltered by the removal of their olfactory organs (Wells and Wells 1956).

Along with vision and chemoreception, cephalopods are equipped with a lateral line system. The lateral line system consists of epidermal hair cells arranged in lines located on the head and arms and is sensitive to water movement (Budelman 1996). This sensitivity allows cephalopods to detect prey in darkness or in murky waters. Behavioral physiological studies lend support to this. For example, Budelman et al. (1991) found that after surgical destruction of 75% of the epidermal lines, the hunting success of cuttlefish in complete darkness diminished to 30% of that of intact cuttlefish. Budelman (1996) has also reported that a cuttlefish that is partially buried is able to detect a moving fish 1 m in size from about 30 m away using the lateral line system.

## Predatory Strategies

Various modes of hunting are used by cephalopods dependent on the species, though hunting strategies can be flexible and there may be an overlap of techniques employed (Hanlon and Messenger 1996). One common hunting strategy is ambushing. Many species of octopus will lie and wait for prey to pass by before attacking. For example, the Atlantic pygmy octopus (*Octopus joubini*) has been seen hiding in empty bivalve shells waiting for prey to pass before reaching out and grabbing them (Hanlon 1983) and the common octopus (*Octopus vulgaris*) has been shown to hide behind stones before attacking passing crabs (Hanlon and Messenger 1996). Squid also

ambush predators. Species of bobtail squid, such as *Sepiola affinis* and *Euprymna scolopes*, hide in the substrate, striking at passing prey (Hanlon and Messenger 1996) and the longfin inshore squid (*Doryteuthis pealeii*) will lie in the sand, camouflaged, and strike at fish passing by (Hanlon and Messenger 1996).

Along with ambushing prey, cephalopods may use a lure, enticing prey close enough to capture. Though there is no conclusive example of cephalopods luring prey, it is speculated that cuttlefish (*Sepia*) and reef squid (*Sepioteuthis*) do so (Hanlon and Messenger 1996). Prior to attacking shrimp, the common cuttlefish and the broadclub cuttlefish (*Sepia latimanus*) often darken and raise their first, and sometimes second, pair of arms, waving them from side to side (Hanlon and Messenger 1996). Reef squid exhibit similar behavior but may also lighten the tips of their tentacles and hold them in a curved position (Hanlon and Messenger 1996). Though it is thought that these behaviors are used to lure prey, it is also possible that these behaviors serve to direct the prey's attention away from the tentacles that will be used in the capture of the prey (Hanlon and Messenger 1996).

Cephalopods have also been known to stalk and pursue prey while hunting. Stalking involves a slow approach to prey before a final, sudden, attack (Hanlon and Messenger 1996). Cephalopods reserve stalking for large, fast prey and utilize different modes of hunting for smaller, slower prey (Hanlon and Messenger 1996). Caribbean reef squid (*Sepioteuthis sepioidea*) stalk fish and shrimp and the northern shortfin squid (*Illex illecebrosus*) often stalk trout (Hanlon and Messenger 1996). Stalking behavior has not been reported in octopuses (Hanlon and Messenger 1996). Pursuit occurs when prey has recognized a predator and flees (Hanlon and Messenger 1996). Two kinds of pursuit are recognized in cephalopods: guided pursuit and ballistic attack (Hanlon and Messenger 1996). During guided pursuit, the predator uses visual feedback to change its pursuit path according to the position of the prey, such as when shortfin squid (*Illex*) pursue trout (Hanlon and Messenger 1996). During ballistic attack, predators establish the

position of prey and propels itself at it on the assumption that the prey will not move (Hanlon and Messenger 1996). Ballistic attack is used by octopuses to catch crabs (Maldonado 1964) and by cuttlefish to catch prawns (Messenger 1968). Pursuit may also involve interception of a prey's flight path (Hanlon and Messenger 1996). Though this behavior has not been demonstrated reliably by cephalopods, it is possible that cuttlefish anticipate the flight path of fish by attacking from the front (Messenger 1968). Cuttlefish will also continue to pursue prey that has moved out of sight, a behavior that has not been reported in any other cephalopods (Hanlon and Messenger 1996).

Although octopuses have an acute sense of vision and are able to make visual attacks on prey, they often engage in speculative hunting (Hanlon and Messenger 1996). During speculative hunting, octopuses will pounce with their web expanded and then feel around under their web for food (Yarnall 1969). This behavior has been observed in many species of octopus, including the Caribbean reef octopus (*Octopus briareus*; Hochberg and Couch 1971), the big blue octopus (*Octopus cyanea*; Yarnall 1969), the common octopus (*Octopus vulgaris*; Mather 1991), and the giant Pacific octopus (*Enteroctopus dofleini*; Hartwick 1983). Octopuses, such as the common octopus, the white-spotted octopus (*Octopus macropus*), and the big blue octopus, may also extend their arms into crevices likely to contain prey in search of food (Hanlon and Messenger 1996). A form of speculative hunting, where sand is pushed around with the arms to uncover buried shrimp, has also been observed in Caribbean reef squid (*Sepioteuthis sepioidea*; Hanlon and messenger 1996).

Lastly, cephalopods may disguise themselves while hunting by making locomotor, postural, textural, and chromatic adjustments (Hanlon and Messenger 1996). For instance, the caribbean reef squid may disguise itself as sargassum weed while it hunts, hiding in the clumps of sargassum before striking at prey (Hanlon and Messenger 1996). The Caribbean reef squid has also been observed swimming backwards while displaying two false eye spots so that it looks like a herbivorous parrotfish (Hanlon and Messenger 1996). In

doing so, the Caribbean reef squid is able to swim amidst and prey upon small reef fish (Hanlon and Messenger 1996). It is speculated that the elaborate body patterns shown by blue-ringed octopuses (*Hapalochlaena*) in association with algae could also be a form of hunting in disguise (Hanlon and Messenger 1996).

## Feeding Behavior

Once prey has been captured, cephalopods must ingest it. Some cephalopods secrete toxins from their posterior salivary glands (Hanlon and Messenger 1996). These toxins are used to immobilize prey while cephalopods prepare them for ingestion (Hanlon and Messenger 1996; Villanueva et al. 2017). Cuttlefish and squid often deliver these toxins via a bite, whereas delivery of toxins by octopuses, which feed mostly on crustaceans and bivalves, is associated with drilling through the shells of bivalves, and the carapace or eyes of crustaceans (Hanlon and Messenger 1996; Villanueva et al. 2017). The use of these toxins has been documented in coleiods, however not all coleiods produce toxins and the extent to which this occurs throughout cephalopods remains unclear (Hanlon and Messenger 1996).

Hard shells protecting bivalves, crustaceans, and other prey present a challenge to those cephalopods, looking to consume the soft tissue inside (Mather and Scheel 2014). Several methods are used by cephalopods to overcome this challenge. Octopuses may use their strength to pull open bivalve shells or, as mentioned earlier, may drill into shells or carapaces using their radula and salivary enzymes (Mather and Scheel 2014; Villanueva et al. 2017). Cephalopods may also chip prey with their beaks (Mather and Scheel 2014) and shell crushing has been reported in the deep-sea octopus *Graneledone* (Villanueva et al. 2017). Cephalopods likely use the most cost-effective behavior based on previous experience, however which behavior is used may also be influenced by a number of factors including cephalopod size and weight, prey size and weight, and beak size (Villanueva et al. 2017).

Due to having small mouths and a narrow esophagus, cephalopods are unable to swallow their prey whole (Hanlon & Messenger). Instead, cephalopods use a combination of their beak, radula (a toothed, tongue like structure), and salivary enzymes to break up their prey (Hanlon and Messenger 1996). Cephalopods show differences in digestion rates that are related to their habitat and lifestyle (Hanlon and Messenger 1996). Bottom dwelling cephalopods, such as *Sepia* and *Octopus* can take from 16–20 h to digest a meal, whereas cephalopods such as *Loligo* and *Ommastrephes*, which actively swim throughout the day and night, may take only 3–6 h to digest (Hanlon and Messenger 1996). There is evidence that some octopuses, such as *Eledone* and *Octopus*, begin digestion of crabs externally, secreting digestive enzymes into the carapace to destroy musculoskeletal attachments (Hanlon and Messenger 1996). No evidence has been found for external digestion in cuttlefish and there is very little evidence for external digestion in squids (Hanlon and Messenger 1996).

## Conclusion

Cephalopod species are diverse and exhibit a wide range of feeding behavior. All cephalopods are carnivores and many species require diets high in lipids and copper (Villanueva, et al. 2017). Most cephalopod species are generalist feeders, preying on a wide variety of animals, from shrimp, mollusks, and crustaceans, to birds and tuna (Anderson and Shimek 2014; Budelmann 1996; Olson et al. 2006). Cannibalism is also common among cephalopods (Ibáñez and Keyl 2010). In general, octopuses have a propensity for feeding on crabs and bivalves, cuttlefish tend to feed mainly on shrimp-like crustaceans and fish, and squid feed on fish, crustaceans, and other cephalopods (Hanlon and Messenger 1996). However, what an individual cephalopod eats at any given time is often a compromise between preference and availability (Hanlon and Messenger 1996).

Cephalopods are equipped with an arsenal of adaptations for detecting, pursuing, and capturing

prey. Cephalopods have advanced nervous systems and use a combination of photo-, chemo-, and mechanoreceptors to acquire information about potential prey (Villanueva et al. 2017). The hunting strategies used by cephalopods varies within and between species and include ambushing, luring, stalking, pursuit, speculative hunting, and hunting in disguise (Hanlon and Messenger 1996). Once prey is captured, some cephalopods inject toxins into their prey to immobilize it (Hanlon and Messenger 1996; Villanueva et al. 2017). How widespread this behavior is throughout cephalopods is unknown and further research, especially in squids, is needed (Hanlon and Messenger 1996).

Cephalopods that prey upon bivalves and crustaceans must first get through hard outer shells in order to feed on the soft tissue inside (Mather and Scheel 2014). Several methods are employed by cephalopods to overcome this obstacle including pulling shells apart (Mather and Scheel 2014), drilling into shells and carapaces (Mather and Scheel 2014; Villanueva et al. 2017), chipping shells with their beaks (Mather and Scheel 2014), and crushing shells (Villanueva et al. 2017). Research on feeding behaviors, and on cephalopod diet in general, has focused on coastal cephalopod species due to their accessibility in the field and their ability to be housed and maintained in laboratory conditions (Villanueva et al. 2017). Conversely, further research on deep sea cephalopods is necessary, as little is known about their feeding strategies and behaviors (Villanueva et al. 2017).

## Cephalopod Life History

Taryn Eaton  
Oakland University, Rochester, MI, USA

### Introduction

The life span of cephalopods varies depending on the species. Most cephalopods live only 1–2 years (Mather and Scheel 2014). The smallest

cephalopods live only a few months (e.g., 3 months for the pygmy squid, *Idiosepius notoides*) while the largest cephalopods can live up to 5 years (e.g., the giant Pacific octopus, *Enteroctopus dofleini*; Mather and Scheel 2014). Cephalopod life span is correlated with size and water temperature, with those species that mature at larger sizes and residing in colder water having longer life spans (Anderson et al. 2002; Mather and Scheel 2014). However, there is a stronger relationship with water temperature than with size (Mather and Scheel 2014). Regardless, all cephalopods “live fast and die young” (Anderson et al. 2002). They hatch from eggs, may go through a paralarval phase, grow quickly, mature, and mate (Anderson et al. 2002). Females of some species brood eggs, and many species experience a senescent state before dying (Anderson et al. 2002). The following text will review the physiological, morphological, and behavioral changes that occur during each phase of the cephalopod life cycle.

### Egg to Paralarvae

The transition from egg to paralarvae is a critical phase within the early life history of cephalopods (Robin et al. 2014). This phase begins at hatching (Robin et al. 2014). The oceanographic environment surrounding eggs affects embryonic development and hatching success (Robin et al. 2014). Cephalopod embryos are vulnerable to thermal fluctuations (Robin et al. 2014). Embryos that experience temperatures outside the optimal thermal range may result in abnormal embryonic development, premature hatching, and mortality (Oosthuizen et al. 2002). Salinity, more so than temperature, has also been shown to affect hatching rate, egg size, and hatching time in cephalopods, with low salinity levels having severe effects on embryonic development and survival (Chung 2003). Hatching conditions in cephalopods are flexible in order to optimize survival posthatching (Boletzky 2003). Hatching periods vary greatly depending on species, ranging from 2 days in *Octopus laqueus* to 78 days in the giant Pacific octopus (*Enteroctopus dofleini*; Robin et al. 2014). Mechanical stimulation of eggs, such as agitation by brooding females, has been

suggested to promote hatching in benthic (i.e., living on the seafloor) octopods under both wild and laboratory conditions (Villanueva and Norman 2008). Environmental factors can also trigger hatching (Robin et al. 2014). For instance, light has been proposed to regulate the hatching process, with most hatching events occurring at night (Villanueva and Norman 2008). Tidal and lunar rhythms are also associated with the onset of hatching (Villanueva and Norman 2008).

Upon hatching, many species of octopus, and some species of cuttlefish and squid, have yet to develop into their adult form and lifestyle (Mather and Scheel 2014). These hatchlings are referred to as paralarvae (Young and Harman 1988). Paralarvae are planktonic (i.e., free-floating among the plankton in open waters; Mather 2006) and exhibit morphological differences from adults (Robin et al. 2014). In many cephalopods, the shape and features of the beak of paralarvae differ from those of adults (Robin et al. 2014). Along with the size of the beak being smaller in paralarvae, many species of octopods, such as the common octopus (*Octopus vulgaris*), the Atlantic pygmy octopus (*Octopus joubini*), the curled octopus (*Eledone cirrhosa*), the paper nautilus (*Argonauta argo*), and the common blanket octopus (*Tremoctopus violaceus*) have a row of teeth on the upper and lower portions of the beak (Robin et al. 2014). The common European squid (*Loligo vulgaris*) and the longfin inshore squid (*Doryteuthis pealeii*) also have toothed beaks, however teeth are only on the lower portion of the beak (Boletzky 1971). Arm and tentacle morphologies may also differ between paralarvae and adults. The paralarvae of the family of squid ommastrephidae have a proboscis that separates into two tentacles as individuals grow and reach adulthood (Robin et al. 2014). Additionally, in cephalopod families such as Onychoteuthidae, Enoploteuthidae, Pyroteuthidae, Ancistrocheiridae, Octopoteuthidae, Gonatidae, and Cranchiidae, some suction rings develop into chitinous hooks which aid in the capture of prey (Engeser and Clarke 1988).

Along with morphological differences, paralarvae exhibit behavioral differences from adults. Paralarvae of all cephalopod species are solitary and social behaviors do not present until later

stages in life (Robin et al. 2014). Most of the behavioral differences are related to feeding, such as prey size and preferences, and predatory behaviors (Robin et al. 2014). For example, newly hatched opalescent inshore squid (*Doryteuthis opalescens*) exhibit a singular basic attack, in which the arms and tentacles are spread apart and thrust forward (Chen et al. 1996). Forty days post-hatching, this basic attack is replaced with arm net and tentacular strike behaviors (Chen et al. 1996). The paralarval stage ends when individuals begin capturing prey and settle into their adult lifestyle (Robin et al. 2014). Many species of cuttlefish, along with deep sea octopus species and some squid species, do not have a paralarval phase (Boletzky and Villanueva 2014; Robin et al. 2014). Upon hatching, these species immediately adopt a benthic lifestyle and begin capturing size-appropriate prey (Mather and Scheel 2014).

## Nonreproductive Adulthood

Depending on whether or not a paralarval phase exists, the juvenile phase of the cephalopod life cycle starts at either the end of the paralarval phase or at hatching (Boletzky and Villanueva 2014). Cephalopod juveniles are often referred to as subadults. A subadult is an individual who appears to be functionally and morphologically similar to an adult but is not yet reproductively mature (Young and Harman 1988). During this time, most cephalopod species are solitary and asocial (Hanlon and Messenger 1996). With that, behavior during this phase is less concerned with members of the same species and more concerned with predatory pressures and finding and consuming prey (Mather 2006). For instance, visual displays during this stage of life are primarily used for camouflage and predator evasion (Hanlon and Messenger 1996). For the few social species of cephalopods, schooling behavior presents in this stage of life. For instance, schooling behavior in the European squid (*Loligo vulgaris*), opalescent inshore squid, longfin inshore squid, and Argentine shortfin squid (*Illex argentinus*) presents between 20 and 60 days after hatching (Vidal et al. 2010).

Minor morphological changes take place during this stage of life. In benthic octopuses with a

paralarval stage, the change from paralarvae to subadult occurs at settlement (Robin et al. 2014). The changes associated with the adoption of a benthic lifestyle include positive allometric arm growth; chromatophore, iridophore, and leucophore growth; the loss of K  lliker organs that cover the surface of the body; and the loss of the lateral line system (Villanueva and Norman 2008). Those cephalopods with toothed beaks during their paralarval stage lose their teeth upon entering the subadult phase (Boletzky and Villanueva 2014). This phase is also marked by sexual differentiation, during which male and female organs grow (Boletzky and Villanueva 2014). Males of most coleoid cephalopods develop a specialization of one or more arm tips, known as a hectocotylus, which is used to transfer spermatozoa to females (Robin et al. 2014). However, not all cephalopods develop a hectocotylus. *Nautilus* spp. develop a large erectile mass known as a spadix (Arnold 1987), and cirrate octopods have no specialization for spermatophore transfer (Mangold 1987). Males of some cephalopod species, such as the big blue octopus (*Octopus cyanea*) and the southern dumpling squid (*Euprymna tasmanica*), develop secondary sexual characteristics, such as extra-large suckers on the second and third arms (Robin et al. 2014). These suckers may be used for displaying to members of the same species (Packard 1961), and/or in chemoreception (Voight 1991). Females of some cephalopod species, such as *Argonauta*, develop specialized dorsal arms which secrete a calcareous (i.e., containing calcium) chamber used for brooding eggs (Robin et al. 2014). Additionally, females of the species *Leachia pacifica* develop brachial photophores that are used to attract mates (Young 1975). Cephalopods transition from subadults to adults with the attainment of sexual maturity (Robin et al. 2014). In coastal cephalopods, sexual maturation is reached in about a year (Mather and Scheel 2014).

## Reproductive Adulthood

Upon reaching sexual maturity, cephalopod behaviors shift from growth related to those

related to reproduction (Mather 2006). Many cephalopods, including octopus and cuttlefish, migrate to specific areas, where they mate and lay eggs (Mather 2006; Robin et al. 2014). The nature and magnitude of migration varies among cephalopod species (Robin et al. 2014). Cephalopods may migrate between inshore and offshore habitats, as is the case with the Patagonian squid (*Loligo gahi*; Arkhipkin et al. 2004); move in and out of current systems, such as the northern shortfin squid (*Illex illecebrosus*; Dawe et al. 2000) and the Japanese flying squid (*Todarodes pacificus*; Sugimoto and Tameishi 1992); or have significant inshore movements, for example the southern calamari (*Sepioteuthis australis*; Pecl et al. 2006). Some open-water cephalopod species, such as *L. pacifica*, *Eledonella pygmaea*, and the clawed armhook squid (*Gonatus onyx*), undergo vertical migrations from near-surface waters to waters at depths of 1,000 m or more (Robin et al. 2014). Regardless of the type or extent of migration, it appears this behavior is associated with increased chances of finding a mate, along with finding a suitable place for egg attachment or release (Robin et al. 2014).

The first indication of sexual behavior in cephalopods is a shift from using visual displays for concealment and predator evasion to courtship and reproductive behavior (Mather 2006). Males of species such as the southern calamari (Jantzen and Havenhand 2003) and the Cape Hope squid (*Loligo reynaudii*; Hanlon et al. 1994) exhibit multiple, complex, chromatic, postural, and locomotor patterns while courting females. Common cuttlefish (*Sepia officinalis*; Boal 1997) and Caribbean reef squid (*Sepioteuthis sepioidea*; Mather 2006) males present an agonistic, striped body pattern, known as the intense zebra display, to other males while courting females. Caribbean reef squid also produce the sexual Saddle (pale mantle with brown ring) and a pre-mating on-off flicker to mature females (Mather 2006). Subadults are also capable of producing these displays, but often produce the displays out of normal sequence or to individuals of the wrong sex (Mather 2006). Aside from visual displays, other complex courting behaviors can be seen in cephalopods.

Some cuttlefish species, including the giant cuttlefish (*Sepia apama*), use a mating strategy known as female mimicry, in which smaller males switch between the appearance of a female and that of a male in order to foil mate-guarding attempts of larger, dominant males (Robin et al. 2014). Additionally, male mourning cuttlefish (*Sepia plangon*) will deceive rival males by displaying male courtship patterns to potential mates on one side of their mantle, while simultaneously displaying female patterns to the rival male on the other, thus preventing the rival from disrupting courtship (Brown et al. 2012). However, not all cephalopods exhibit such elaborate courtship behaviors. Most octopods display little or no courtship behaviors before mating.

Direct female mate choice occurs in cuttlefish (Robin et al. 2014). However, the traits and ornamentations selected for by females are not well defined (Robin et al. 2014). Boal (1997) found that female common cuttlefish show consistent preferences for the most recently mated males and those showing fewer zebra displays, as opposed to males whose characteristics correlated to male dominance (e.g., body patterning and size). Boal (1997) suggested that olfactory cues, as opposed to visual cues, are used by female cuttlefish for assessing males to mate with. Female giant cuttlefish have also been observed actively rejecting mating attempts (Robin et al. 2014). No clear female mate choice has been observed in octopuses (Robin et al. 2014). Females of many cephalopod species, including loliginid squid and cuttlefish, may mate with and store spermatophores from multiple males (Robin et al. 2014; Mather and Scheel 2014). Once sperm is stored, females may actively influence which sperm is used to fertilize their eggs, leading to multiple paternity within egg strings (Mather and Scheel 2014).

Once a mate has been chosen, copulation occurs, during which the male inserts his hectocotylus into the female's mantle cavity and deposits his sperm, where it is stored until the female is ready to fertilize her eggs (Mather and Scheel 2014). Females release eggs from their oviduct, fertilize each one using stored sperm, and encases them in a protective layer (Robin et al. 2014). Cuttlefish often deposit their eggs

on supports, such as in crevices among corals (Mather and Scheel 2014). Squid deposit large egg masses on or under bottom substrate, such as in sand or under rocks (Mather and Scheel 2014). The majority of cuttlefish and squid species do not provide parental care to their offspring, though brooding behavior has been seen in the Gonatidae and Bathyteuthida squid families (Mather and Scheel 2014; Robin et al. 2014). Most species of octopus deposit their eggs by cementing them inside the roof of their dens (Mather and Scheel 2014). Those species of octopus that do not reside in dens or shelters, such as the brown striped octopus (*Octopus burryi*) and the wonderpus octopus (*Wunderpus photo-genicus*), carry their developing eggs in the web of their arms (Robin et al. 2014). Octopuses then exhibit egg-brooding behaviors, such as manipulating each egg strand and blowing jets of water across them to clean and oxygenate them (Mather and Scheel 2014). Female octopuses will continue to brood their eggs until hatching or until they die (Mather and Scheel 2014).

## Senescence

Senescence is a stage in the cephalopod's life cycle that often occurs shortly after mating and before death (Anderson et al. 2002). Upon reaching sexual maturity, cephalopods' digestive glands cease to function properly, and they slow their feeding or stop eating entirely (Anderson et al. 2002; Mather 2006). It has been postulated that starvation is what ultimately leads to the cephalopod's death during this stage (Anderson et al. 2002). As cephalopods begin to lose weight, their bodies shrink, causing the skin around their eyes to retract (Anderson et al. 2002). White lesions may appear on the skin of senescent cephalopods (Anderson et al. 2002; Mather 2006). These skin lesions can easily become infected due to healing processes being shut down during senescence (Anderson et al. 2002). The brain tissue in senescent cephalopods deteriorates, resulting in undirected and uncoordinated activity (Anderson et al. 2002) and the attenuation of behavioral sequences (Mather 2006). Chichery and Chichery (1992) found that cuttlefish first

underestimated the distance of prey, resulting in undershooting with their tentacles, then detected but failed to pursue prey, and finally stopped orienting towards prey completely during a 2 week period of decline during senescence. Additionally, 2 year old cuttlefish were slower to learn an avoidance task, had less retention of the task, and were more variable in their learning than 1 year old cuttlefish. An examination of the nervous system showed axon degeneration in the senescent cuttlefishes' brains, especially in the motor centers of the peduncle area and basal lobes (Chichery and Chichery 1992). There was also degenerating fibers in the tracts leading to and from the vertical lobe (Chichery and Chichery 1992). The degeneration of these motor output areas correlates well with the decline in response to prey found in cuttlefish (Mather 2006). In an experiment to evaluate hormonal control over senescence, Wodinsky (1977) removed the optic gland in brooding, female Caribbean two spotted octopus (*Octopus filusus*). He found that those females with their optic gland removed stopped brooding, began to eat again, and lived longer than females that still had their optic gland. This experiment has yet to be performed with male octopuses.

## Introduction

With approximately 700 species, cephalopods exhibit a wide range of forms (Budelmann 1994). However, all these forms have a similar, molluscan body plan, with a head, a foot, and a visceral mass covered by a mantle (Hanlon and Messenger 1996). The cephalopod head is markedly developed, with the largest brain of any invertebrate and sophisticated sense organs (Hanlon and Messenger 1996). The cephalopod foot has developed into a funnel, as well as eight arms found in all coleoids (i.e., octopus, squid, and cuttlefish) and tentacles found in decapods (i.e., cuttlefish and squid) and *Nautilus* (Hanlon and Messenger 1996). The mantle forms a sheltered space around the viscera (which includes circulatory, digestive, excretory, and reproductive systems), known as the mantle cavity (Hanlon and Messenger 1996). The mantle cavity contains the gills (2 in coleoids and 4 in *Nautilus*) and is where the gut, kidneys, and gonads open into (Hanlon and Messenger 1996). In most mollusks, the mantle also secretes a protective shell (Hanlon and Messenger 1996). However, among living cephalopods the shell has been internalized (such as in decapods) or lost completely (such as in octopods; Hanlon and Messenger 1996). Only *Nautilus* has retained an external, chambered shell which is used for protection and buoyancy (Hanlon and Messenger 1996). The following text will review the morphology of cephalopods and address gaps of knowledge.

## Cephalopod Morphology

Taryn Eaton  
Oakland University, Rochester, MI, USA

### Definition

**Morphology** The branch of biology that deals with the form of living organisms, and relationships between their structures.

## The Nervous System

The cephalopod nervous system is the most complex of any invertebrate (Budelmann 1995) and can be divided into three parts (Hochner 2004). The first part is the central brain (Hochner 2004). In coleoids, the central brain contains 40–45 million nerve cells and surrounds the esophagus (Hanlon and Messenger 1996; Hochner 2004). The central part of the brain can be divided into sub-, peri-, and supraesophageal areas, which can be broken down further into 25 major lobes (Budelmann 1995). A few of these lobes are

further subdivided, giving a total number of 37 lobes in octopods (i.e., octopus) and 38 lobes in decapods (i.e., cuttlefish and squid; Young 1971). These lobes vary in size from species to species and most do not have an individual, exact function (Budelmann 1994). In general, the subesophageal lobes are lower motor centers and the peri- and supraesophageal lobes are intermediate and higher motor centers, as well as associative centers for learning and memory (Budelmann 1994). The *Nautilus* brain is simpler than coleoid brains (Budelmann 1995). It is made up of a system of three ganglionated nerve cords: a supraesophageal cerebral cord, and an anterior and posterior subesophageal cord, which are subdivided into 12 lobes (Budelmann 1995). The *Nautilus* brain lacks the structures for intricate motor control of the arms (Budelmann 1995). Additionally, the centers dedicated to learning and memory in the coleoid brain, and the giant fiber system in decapod brains, are absent in *Nautilus* (Budelmann 1995; Hanlon and Messenger 1996).

The other two parts of the nervous system, the optic lobes and the peripheral nervous system, are located outside the brain and are autonomous systems (Hochner 2004). The optic lobes are lateral to the central brain (Hanlon and Messenger 1996) and contain between 120 and 180 million nerve cells (Hochner 2004). The size of the optic lobes varies from species to species and is correlated to the size and complexity of the eyes (Budelmann 1996). Generally, the optic lobes are smaller in octopods than in decapods (Budelmann 1996). The optic lobes analyze visual input and regulate visual behavior (Budelmann 1995). They also store visual memory (Hanlon and Messenger 1996) and are the centers for visual discrimination learning (Budelmann 1995). The peripheral nervous system is distributed along the arms and contains 350 million nerve cells (Budelmann 1995). It is made up of five brachial nerve cords, with each nerve cord having one large axial cord, four smaller, peripheral, intramuscular cords, and as many brachial ganglia as suckers (Budelmann 1995). Each sucker also has its own sucker ganglion (Budelmann 1995). Many of the neurons in

the peripheral nervous system are lower motor neurons that control the muscles of the suckers (Budelmann 1995). The peripheral nervous system also processes sensory information gathered by several million sensory cells in the skin and suckers of each arm (Hochner 2004).

## Sense Organs

### Mechanoreceptors

Cephalopods are sensitive to tactile stimuli over the entirety of their body (Hanlon and Messenger 1996). Several types of mechanoreceptors have been described in the rim of the suckers in octopods and decapods (Graziadei 1971). The tactile information gathered by the suckers travels to the highest centers of the brain for learning (Hanlon and Messenger 1996). It has been shown that *Octopus* can readily learn to discriminate objects with different textures (Wells 1961). However, *Octopus* cannot be trained to discriminate between objects with equally irregular surfaces, differing only in the allocation of irregularities, or between objects with the same texture but different shape using only tactile information (Wells 1961). This is because *Octopus* lack awareness of the position of their suckers in space (i.e., proprioceptive information), which is likely due to the arms lacking joints and being extremely flexible (Wells and Wells 1957). Along with the mechanoreceptors in the suckers, decapods and octopod hatchlings have rows of epidermal hair cells on their head and arms that can detect local water movement (Budelmann et al. 1991). These rows of hairs are known as the lateral line system (Budelmann et al. 1991). Behavioral data indicate that the lateral line system is used in prey detection (Budelmann et al. 1991), allowing decapods to detect a fish 1 m in length from a distance of 30 m (Budelmann 1994, 1996). It is likely that the lateral line system is also used in predator detection and avoidance and schooling behavior, but this remains to be seen (Budelmann 1994).

Cephalopods also have a specialized set of mechanoreceptors known as statocysts (Budelmann 1994). Statocysts are a set of organs located in the cartilage below the brain, that gather

information used in equilibrium control, similar to the vestibular system in vertebrates (Budelmann 1994). *Nautilus* statocysts are simple, oval-shaped cavities, lined with hair cells and are used as a gravity receptor system (Budelmann 1994). Statocysts in octopods and decapods contain two receptor systems (Hanlon and Messenger 1996). The macula–statolith–statoconia system gathers information about the direction of gravity and linear acceleration (Hanlon and Messenger 1996) and regulates countershading reflexes (Hanlon and Messenger 1996). The crista-cupula system gathers information about angular acceleration (Budelmann 1994). The information gathered by both receptor systems is used to govern the orientation of the head, eyes, funnel, and body (Hanlon and Messenger 1996). Surgical destruction of both statocysts causes cephalopods to spiral and zigzag in all three planes as they swim (Boycott 1960). The statocysts also provide the brain with information on infrasound (i.e., low-frequency vibration; Hanlon and Messenger 1996). Whether or not cephalopods can actually “hear” has been of much debate. Attempts made by Hubbard (1960) to train octopuses to respond to frequencies of 100 Hz, 900 Hz, and 2,000 Hz were unsuccessful. However, Packard et al. (1990) trained *Sepia*, *Loligo*, and *Octopus* to associate sound stimuli between 1 Hz and 100 Hz with a small electrical shock, with the most sensitive part of the frequency range being below 10 Hz. Packard et al. (1990) suggest that cephalopods can sense low-frequency sound using particle motion detection via the statocysts rather than sound pressure. Whether this can be considered hearing is a problem of definition (Hanlon and Messenger 1996). If using a narrow definition, cephalopods cannot hear, as they lack air-filled cavities and the associated sensory structures that can be compressed by the pressure wave of underwater sound (Budelmann 1994).

### Chemoreceptors

Cephalopods can detect chemical signals using two chemoreceptor systems: a chemotactile sense and distant chemoreception (Budelmann 1996). The receptors involved in contact chemoreception are in the distal region of the long digital

tentacles of *Nautilus* (Budelmann 1996) and in the buccal lips, mouth, and suckers of octopods and decapods (Graziadei 1964). There are about 10,000 chemoreceptors in each sucker in octopods, totaling 16 million receptors per animal (Graziadei 1964). In contrast, cuttlefish have only 100 chemoreceptors per sucker (Graziadei 1964). This difference may be because octopods, but not decapods, use their arms and suckers to look for food in out-of-sight habitats (Budelmann 1994, 1996). The ability of the common octopus (*Octopus vulgaris*) to “taste by touch” was investigated by Wells (1963), who found that octopus can distinguish between porous objects soaked in plain seawater and seawater with hydrochloric acid, sucrose, or quinine sulfate added by touch. Further, they were able to detect these substances in concentrations 10–1,000 times lower than the human tongue can (Wells 1963). Additionally, Wells and Wells (1956) found that the responses of blind octopuses to sardine blood were unaltered by the removal of the olfactory organs.

The organs involved in distant chemoreception are the rhinophores in *Nautilus* and the olfactory organs in octopods and decapods (Budelmann 1996). Rhinophores are elongated, sac-like structures lined with two types of ciliated cells and are located below the eye (Budelmann 1996). The rhinophores allow *Nautilus* to detect and follow odor trails to their source in three dimensions (Basil et al. 2000). If the rhinophores are blocked, either uni- or bilaterally, *Nautilus* is still able to detect odor using its tentacles but is not able to guide orientation behavior toward the odor source (Basil et al. 2000). Like rhinophores, the olfactory organs in octopods and decapods are located below and behind the eye, and contain five types of ciliated cells (Budelmann 1996). Behavioral studies have demonstrated the importance of distant chemoreception in varying aspect of cephalopod ecology. For instance, distant chemoreception is an important aspect in prey detection (Hanlon and Shashar 2003) and conspecific odor perception (Hanlon and Shashar 2003; Walderson et al. 2011). Distant chemoreception also plays a role in the reproductive behavior of some cephalopods. Female chambered nautilus (*Nautilus*

*pompilius*) are attracted to the odor of males and extend their tentacles fully when tracking male odors (Basil et al. 2002), while sexually mature males are attracted to females by excretions of the rectum (Westermann and Beurlein 2005). It has been suggested that chemical signals intercepted by the olfactory organs and integrated in the olfactory lobes could initiate the shift from growth-related behaviors to those related to reproduction in the common octopus (Polese et al. 2015), but this has yet to be tested.

### Photoreceptors

Cephalopods are known for their well-developed eyes and complex visual behavior (Budelman 1994, 1996). In *Nautilus*, the eyes lack a lens and function similarly to pinhole cameras (Budelman 1994). However, the eyes of most cephalopods resemble those of vertebrates (Hanlon and Messenger 1996). However, the retina is much simpler in cephalopod eyes, with only two neural components and no separation into rods and cones (Budelman 1994; Hanlon and Messenger 1996). The eyes of cephalopods contain only one visual pigment, suggesting that cephalopods lack color vision (Hanlon and Messenger 1996). The single exception being the firefly squid (*Watasenia scintillans*), whose eyes contain at least three visual pigments (Matsui et al. 1988) indicating the firefly squid may have color vision (Hanlon and Messenger 1996; Matsui et al. 1988). Though unable to see color, cephalopods can see the plane of polarized light (Budelman 1994).

Cephalopods also have photoreceptors other than the eyes (Hanlon and Messenger 1996). Photoreceptor organs have been described on the head of hatchling squid and cuttlefish and photosensitive vesicles (PSV) are present in coleoids (Hanlon and Messenger 1996). The PSV are especially well developed in mid- and deep-water cephalopods (Young 1977). Though their function is not well understood, Young (1977) posited that the PSV may monitor the downwelling light to regulate the light mid- and deep-sea cephalopods emit from their own photophores. It has also been suggested that the PSV could be involved in diel vertical migration of some cephalopods (Hanlon and Messenger 1996).

## Effectors

### Muscles

Effectors are organs of the body that carry out the response an animal makes to a stimulus (Hanlon and Messenger 1996). The most common effectors are muscles (Hanlon and Messenger 1996). When looking at behavior, cephalopods have seven main muscle groups that form six major structures: the fins, mantle, funnel, head and eyes, arms and tentacles (see next section), and the skin (see section “Skin”; Hanlon and Messenger 1996). Fins are present in all decapods, in *Vampyroteuthis*, and in cirrate octopods and are used to help the animal swim (Hanlon and Messenger 1996). The shape and size of cephalopod fins differ depending on the way the animal moves (Hanlon and Messenger 1996). Benthic cephalopods may also use their fins to help bury and conceal themselves in the sand (Hanlon and Messenger 1996). The muscles of the mantle play an important role in jet propulsion and respiration (Hanlon and Messenger 1996). The main function of the funnel is to steer cephalopods (Hanlon and Messenger 1996). However, the funnel also aids in burying benthic cephalopods, can be used to jet water at prey or predators, and is used by female octopuses to aerate and clean their eggs (Hanlon and Messenger 1996). Head movement is also important in steering, whereas eye movements are important for localizing predators and prey (Hanlon and Messenger 1996).

### Arms and Tentacles

All coleoids have eight arms that extend from the head (Hanlon and Messenger 1996). Coleoids use their arms for handling prey, manipulation of objects, locomotion, and reproduction (Kier 2016). Octopods also use their arms for grooming, burying, defense, chemosensing, and tactile sensing (Kier 2016). Decapods have two additional appendages, termed tentacles, which are specialized for prey capture (Hanlon and Messenger 1996; Kier 2016). Octopod arms undergo significant, active elongation and shortening, are capable of intricate and diverse bending and curling movements, and can control stiffness (Kier 2016). Unlike octopod arms, decapod arms do not

undergo significant length change (Kier 2016). However, decapod tentacles are capable of rapid elongation (Kier 2016). The arms and tentacles are lined with complex organs known as suckers (Hanlon and Messenger 1996). Sucker morphology and innervation differs between octopods and decapods (Hanlon and Messenger 1996). The musculature of the suckers allows for strong adhesion and the small ganglion below each sucker coordinates motor and sensory information (Graziadei 1971).

*Nautilus* spp. have 90 thin tentacles, which are considerably different from those of coleoids (Hanlon and Messenger 1996). The tentacles are organized into three groups: a pair of postocular and preocular tentacles, a variable number of labial tentacles surrounding the buccal mass, and 19 pairs of digital tentacles that surround and extend beyond the labial tentacles (Kier 1987). The tentacles are composed of an extendable cirrus enclosed in a protective sheath (Kier 1987). The cirri of the ocular tentacles are thought to be sensory, with the preocular tentacles being chemosensory and the cirri of the postocular tentacles likely containing mechanoreceptors, though their actual function is unknown (Hanlon and Messenger 1996; Kier 1987). The digital tentacles are used to capture and manipulate prey and to attach to surfaces (Kier 1987). The cirrus of both the ocular and digital tentacles have fine, circular grooves and secrete a glycoprotein that make the tentacles adhesive (Hanlon and Messenger 1996). The labial tentacles are mainly used in reproductive behavior (Hanlon and Messenger 1996; Kier 1987). Some of the labial tentacles are modified to form sexual organs, such as the male spadix which is used to transfer spermatophores during copulation (Hanlon and Messenger 1996).

### Skin

The skin of cephalopods contains multiple effectors that enable cephalopods to have remarkable camouflage abilities. Among these effectors are two musculature systems: the skin papillae and chromatophores (Hanlon and Messenger 1996). Skin papillae, which are found in octopods and some decapod species, allow for changes

in skin texture (Hanlon and Messenger 1996). Chromatophores are complex organs consisting of a sacculus containing pigment granules, surrounded by 15–25 radial muscles (Hanlon and Messenger 1996). The pigments contained in the sacculus include red, orange, yellow, brown, and black (Hanlon and Messenger 1996). Chromatophores can be expanded or contracted, creating patterns on the skin (Hanlon and Messenger 1996). The number and density of chromatophores vary between species; however, cephalopods with more intricate patterning repertoires have higher densities of chromatophores, and *Nautilus* spp. have no chromatophores (Hanlon and Messenger 1996).

The skin also contains reflecting cells and photophores (Hanlon and Messenger 1996). There are at least three different reflecting cells found in the dermis, around the eyes and ink sac, and in the photophores (Cloney and Brocco 1983). Iridophores are responsible for the blue and green coloration in cephalopods, though they may also reflect pinks, yellows, and silvers (Cloney and Brocco 1983). Reflector cells, which are known only in octopods, also reflect blues and greens (Cloney and Brocco 1983). Leucophores are broad-band reflectors that provide the “white spots” found in some cephalopod species (Cloney and Brocco 1983). Though they look white under white light, leucophores will appear blue in blue light and yellow in yellow light (Hanlon and Messenger 1996). The ability of the leucophores to reflect the predominant wavelength in the environment is important for achieving color resemblance to the background when camouflaged (Hanlon and Messenger 1996). Photophores are light organs that can produce a steady glow or occasional flashes of light (Hanlon and Messenger 1996). Photophores are used in ventral counter-illumination and signaling, though little is known about how they are controlled (Hanlon and Messenger 1996).

### Buccal Mass

The buccal mass is in the center of the arms and is comprised of the beak, the radula, and the salivary papilla and glands (Hanlon and Messenger 1996). Cephalopod beaks are chitinous and contain

strong musculature (Hanlon and Messenger 1996). Beaks vary significantly among cephalopods and features of the lower beak are different enough to allow taxonomic identification at the generic and/or species level (Clarke 1986). The radula is a toothed ribbon that carries food toward the esophagus and is used by some octopods to drill through mollusk shells and the exoskeletons of crustaceans (Hanlon and Messenger 1996). The salivary papilla, which lies just below the radula, is also used for drilling. It is muscular, and its anterior face is covered with small teeth (Nixon 2009). It also carries the duct from the posterior salivary gland, whose secretions, when delivered to the drilling site, aid in breaking down mollusk shells and the exoskeletons of crustaceans (Hanlon and Messenger 1996). What exactly these substances are is not yet known (Hanlon and Messenger 1996).

### Ink Sac

The ink sac contains the ink gland and a reservoir with sphincters (Hanlon and Messenger 1996). Cephalopods can produce thick clouds of ink that are used as smoke-screens or as pseudomorphs (small mucus-bound blobs that act as decoys) against predators (Hanlon and Messenger 1996). The ink may also act as an alarm substance for other nearby cephalopods (Hanlon and Messenger 1996). Cephalopods that live at great depths, such as *Vampyroteuthis*, cirrate octopods, and some deep-water genera of the family Octopodidae, as well as *Nautilus*, do not have ink sacs (Hanlon and Messenger 1996).

## Cephalopod Sensory Systems

Carly A. York

School of Natural Sciences, Lenoir-Rhyne  
University, Hickory, NC, USA

### Introduction

Cephalopods, the group of invertebrates that contain the octopus, squid, cuttlefish, and *Nautilus*, exhibit wide diversity in form and habitat. The smallest cephalopod is a mere 1.5 cm (*Idiosepius*), with the largest reaching up to 18 m (*Architeuthis*). They inhabit nearly every part of the ocean, from shallow waters to the deep sea

(Hanlon and Messenger 1996). As such, cephalopods require a variety of means for sensing predators, detecting prey, and finding mates. One of the greatest advantages that the cephalopods have in navigating their environment is the ability to utilize multiple sensory modalities to access their surroundings. The most prevalent sensory systems in cephalopods include (1) photoreception with well-developed camera eyes; (2) mechanoreceptors that respond to water movements, pressure, and touch; and (3) chemoreception through olfaction and chemotactile sense (Budelman 1996). Through the acquisition of a variety of sensory information, cephalopods have thrived and proliferated for millions of years, making them one of the most successful animals in the ocean.

### Photoreception

With few exceptions, the eyes are the most prominent sensory features of cephalopods (Budelman 1996), with the optic lobes being the most dominant region of the brain (Young 1962). Resembling the vertebrate eye, the cephalopod eye incorporates a large posterior chamber, lens, iris, retina, choroid, sclera, and argenta (Budelman 1994). However, there are several key differences between the cephalopod and vertebrate eye anatomy. Cephalopods have a rhabdomeric structure of the retina in which there are no rods or cones, as found in other mollusks and arthropods (Mäthger et al. 2009). The visual image also falls directly on the photoreceptor cells without interneurons, as found in the retina of vertebrates (Budelman 1994). The photoreceptors contain only one visual pigment peaking in spectral sensitivity around 480–500 nm. One exception is the firefly squid, *Watasenia scintillans*, which has been found to have no fewer than three pigments (Budelman 1996; Hanlon and Messenger 1996). By having only one visual pigment, cephalopods are technically rendered color-blind, which has been supported through behavioral studies (Mäthger and Hanlon 2006). Recent studies, however, have used computer modeling to suggest that

even with a single photoreceptor, cephalopods can achieve color discrimination through the principle of chromatic aberration, whereby different wavelengths come to focus at different distances behind the lens (Stubbs and Stubbs 2016). Unlike the eyes of most teleost fish, cephalopods have motile pupils that respond to changes in illumination, and the time required for pupil closure is far less than in most other animals. The common cuttlefish (*Sepia officinalis*) and brief squid (*Lolliguncula brevis*) require only 0.32 s and 0.49 s, respectively, to attain half maximal constriction, while the fastest teleost fish response is 0.75 s (Douglas et al. 2005). Cephalopods have laterally placed eyes and consequently see their environment monocularly. As the eyes are utilized individually, the pupils of squid, cuttlefish, and octopus respond independently to light (Douglas et al. 2005). The highly evolved visual system of cephalopods likely plays a large role in predator detection and successful escape (York and Bartol 2016).

## Mechanoreception

In addition to their complex visual system, cephalopods can detect disturbances from small water movements using mechanoreceptors on their head and arms (Bleckmann et al. 1991). Octopods, cuttlefishes, and squids have a receptor system equivalent to the lateral line system of fishes (Budelman and Bleckmann 1988). In the squid *Loligo vulgaris*, five epidermal lines are present on each side of the head running in an anterior-posterior direction (Budelman and Bleckmann 1988).

The cephalopod lateral line system is not as well described as the fish lateral line, but consists of polarized epidermal hair cells that have several kinocilia and an axon extending from their base (Budelman and Bleckmann 1988). Polarization occurs in a precise pattern (anteriorly, posteriorly, left, and right), allowing the animals to respond to water movements as low as 18.8  $\mu\text{m/s}$ , which is equivalent to the sensitivity of fish lateral lines (Douglas et al. 2005). It has been shown that the lateral line plays a role in predator detection and

successful escape responses at the paralarval (hatchling) stages, as well as aiding visual cues in juvenile and adult squid (York and Bartol 2014; York et al. 2016).

In addition to the lateral line system, cephalopods are highly sensitive to touch. In the octopus, suckers on their arms pass on tactile information to the brain. Behavioral experiments have shown octopus discriminate between surface textures and shapes (Wells and Wells 1956). It has been suggested that the cephalopod brain differentiates textures through the proportion of mechanoreceptors stimulated through the suckers (Wells and Wells 1956). The capability of the octopus to learn tactile information appears to be associated with two lobes in their brain, the inferior frontal and subfrontal lobes. Interestingly, these lobes are not present in the cuttlefish or the squid (Hanlon and Messenger 1996).

As in vertebrate systems, the cephalopods have paired organs in the cartilage of the brain, called statocysts, that provide the necessary information about gravity and acceleration required for maintaining proper body orientation while swimming (Budelman 1994). Additionally, the statocysts are responsible for camouflaging the animal through behavior that incorporates the contraction of chromatophores on the ventral side of the animal, breaking up the outline of their body and making visual detection from below more difficult (Budelman 1996). When the statocysts are surgically removed, animals perform erratic swimming behaviors and cannot maintain proper swimming orientation (Budelman 1994). The decapods (squid and cuttlefish) and octopods have major differences within their statocyst systems. Both cephalopod groups have statocysts with a *macula-statolith-statoconia* system and a *crista-cupula* system, each relying on polarized hair cells to detect mechanical disturbance (Budelman 1994).

The macula system uses information of gravity and acceleration to regulate the orientation of the head, eyes, and body, as well as the countershading response. In the decapods, there are three maculae in each statocyst, while in octopus, only one is present, which is likely a reflection of the different ecologies of these groups (Hanlon and

Messenger 1996). The crista system provides information about rotational acceleration, which enables the animal to regulate the position of the head, funnel, and eyes (Budelmann et al. 1987). In decapods, four cristae sit at right angles to each other, allowing the cristae to be stimulated differentially when the animal rotates in the pitch, yaw, or roll axis. Octopods, alternatively, have nine cristae.

Additionally, there are differences in the organization of statocysts of different cephalopod species, which are seemingly correlated to locomotive lifestyle (Young 1984). For example, in the fast-swimming squid groups, the loliginids and ommastrephids, the statocysts form canals which slow down the movement of fluid over the hair cells, making them less sensitive and therefore better suited to measure the effects of rapid body movements. Alternatively, deep-sea neutrally buoyant squid, which move slowly and steadily, have statocysts in which the canals are not present (Hanlon and Messenger 1996).

The statocysts are also the most probable organ for sound detection in cephalopods (Budelmann 1990). While it has long been shown that cephalopods are sensitive to low-frequency vibrations (below 10 Hz) (Packard et al. 1990), newer studies suggest that squid and octopods might detect sound up to 1600 Hz (Hu et al. 2009). Mooney et al. (2010) used auditory evoked potentials with electrodes placed near the statocysts to measure physiological responses to both low- and high-frequency sound waves. Their results suggest that squid detect sound within the same range as most fish, with the statocyst acting as an accelerometer to allow squid to detect the particle motion component of a sound field (Mooney et al. 2010).

## Chemoreception

Cephalopod chemoreception also provides an important source of sensory information (Nilsson et al. 2012). Cephalopods are able to detect chemical cues in two ways: (1) through either contact, using receptors on their arms (Graziadei 1965), or (2) distant chemoreception

(Boyle 1983). In cephalopods, the known chemical sensory epithelia are buccal lips and mouth, isolated sensory neurons all over the body surface, arm suckers, and olfactory organs (Di Cosmo and Polese 2017). These sensory neurons appear to act as a sophisticated system that plays a vital role in navigating their environment (Boyle 1983; Gilly and Lucero 1992).

In the octopus, there are approximately 10,000 primary receptors on each sucker on the animal's arm. Given that an octopus has approximately 200 suckers on each arm, there are 16 million sensory cells per animal (Graziadei 1964). Research suggests that with these receptors, the octopus is capable of discriminating between substances at concentrations 10 to 1000 times lower than humans (Wells 1963; Wells et al. 1965). Behavioral studies indicate the use of distant chemoreception, where the addition of fish scent to water causes predatory movements in octopus (Wells 1963) and in cuttlefish (Messenger 1977). It is also possible that chemosensory cues are used in predator avoidance (Hanlon and Messenger 1996). Gilly and Lucero (1992) found that in restrained squid, L-DOPA and dopamine, which are chemicals found in squid ink, stimulated an escape response. These findings suggest that ink might be used as a conspecific warning in predator avoidance.

## Conclusions

Cephalopods are extremely mobile and fast moving predators, as well as highly sought after prey source, requiring an advanced and effective range of sensory modalities. Compared to their phylogenetic relatives, it is not surprising that cephalopods have the most sophisticated nervous and sense organs of all invertebrates (Packard 1972). While the sensory abilities differ by taxa and ecological niche, cephalopods have extremely versatile means of navigating their environment through combinations of mechanoreception, photoreception, and chemoreception, which have contributed to their success since the Cambrian era (Hanlon and Messenger 1996).

## Ceprano (A “Transitional” *Homo calvarium*)

Giorgio Manzi

Department of Environmental Biology, Sapienza  
Università di Roma, Rome, Italy

Ceprano is a human calvarium (calvarium, or *calvaria*, means a cranium without facial bones) that was occasionally found in several fragments in March 1994 near the homonymous town in southern Latium, Italy (Fig. 1). When discovered, a geo-stratigraphic approach was performed at the regional level and suggested an age of the layer of deposition close to 800–900 ka (Ascenzi et al. 1996, 2000). According to this date, in the mid-1990s, Ceprano contributed to the denial of the so-called short chronology for the earliest inhabitants of Europe (Manzi et al. 2001). In addition, the archaic features of the specimen were related to Mode 1 techno-complexes scattered in various sites across the Ceprano basin, albeit there are also

Acheulean assemblages in the same area (Ascenzi et al. 1996; Biddittu et al. 2020).

Starting from 2001, a project of field studies was developed for almost a decade, with the aim to validate the previous geo-chronological model and improve the available paleontological and archaeological records. In contrast to the expectations, the results of this multidisciplinary work consistently showed that Ceprano is more recent than previously believed, pointing to a time range close to the beginning of MIS 11, that is, between 430 and 385 ka (Manzi et al. 2010). It was also pointed out that the Ceprano hominin died in a floodplain environment with a low topographic gradient, where a fluvial meandering channel occurred after the retreat in extension of the ancient Lirino Lake (Manzi et al. 2010; Di Vincenzo et al. 2017; Biddittu et al. 2020).

The reconstruction of the human calvarium from dozens of fragments (Fig. 2) required the combined efforts of various experts and, overall, about 5 years (Ascenzi et al. 2000). After a first attempt described in 1996, a revised one was obtained in 1999, which has been then accurately re-evaluated, documented (including a microCT-scan recording), and published in various international journals (e.g., Manzi et al. 2001).

From a taxonomic point of view, Ceprano was originally considered to be a European representative of *Homo erectus* sensu lato (Ascenzi et al. 1996; Clarke 2000), whereas in more recent papers its affinities were reconsidered (Ascenzi et al. 2000; Manzi et al. 2001; Mounier et al. 2011), arguing that only less than two-thirds of its character states are consistent with those that are commonly observed in *Homo erectus* and/or in *Homo ergaster* – to such an extent that the variability of these taxa considerably increases when Ceprano is added – while other traits appear more derived.

For a proper phylogenetic interpretation of Ceprano, it is necessary to take into account that different sources of data consistently point out to the time window between 1.0 and 0.5 Ma for the emerging of a derived kind of *Homo* (i.e., distinct from *Homo ergaster/erectus*). This discontinuity most probably originated in Africa (Profico et al. 2016), from where these new humans started to spread across Eurasia, together with the

**Ceprano (A “Transitional” *Homo calvarium*), Fig. 1** Location of the site where the Ceprano calvarium was discovered in 1994, along the Latina Valley near the town of Ceprano, approximately 100 km southeast of

Rome; the gray area corresponds to the inferred maximum extension of the Lirino Lake during the Early/Middle Pleistocene (Biddittu et al. 2020)

Acheulean techno-complexes they made (Biddittu et al. 2020). This humanity is referred by many authors to a polymorphic and widespread single species; priority rules confer to this *taxon* the name of *Homo heidelbergensis*. In addition, in view of the occurrence of different lineages that are recognized during the Middle Pleistocene as belonging to such a putative species, it has been suggested the identification of chrono-geographic varieties or subspecies (i.e., potential incipient species) of *Homo heidelbergensis* (Manzi 2016).

Given this scenario, although the broad architecture of the Ceprano calvarium is close to the general shape that is shared by fossils referred to *Homo erectus* (*sensu lato*), a number of discrete features may be viewed as derived, suggesting a connection with other humans of the Middle Pleistocene. Moreover, Ceprano does not display any Neanderthal trait, differently from a great part of the European samples of the Middle Pleistocene, whereas it shows affinities with penecontemporaneous African specimens (Manzi et al. 2001;

Bruner and Manzi 2007; Mounier et al. 2011). Therefore, its peculiar morphology exhibits a unique combination of archaic and derived features that suggests a puzzling scenario of human evolution in Europe, which involves the occurrence of a considerable phenetic diversity beforehand the evolution of *Homo neanderthalensis*, but concurrently with samples clearly belonging to the Neanderthal lineage (Manzi et al. 2001; Manzi 2016).

In this light, Ceprano documents the occurrence of an archaic variety of *Homo heidelbergensis*, whose cranial morphology was partially lost along the subsequent trajectory of human evolution in Europe. By contrast, this morphology was preserved elsewhere: namely, in Africa and in mainland Asia. Given this scenario, the hypothesis is that the Italian specimen was confined in an eco-geographical *refugium* and retained features of the ancestral stock of *Homo heidelbergensis*. This original morph, in turn, gave rise to the hominin variability observed during the Middle Pleistocene and was ancestral to modern humans

**Ceprano (A “Transitional” *Homo* calvarium), Fig. 2** The Ceprano calvarium (above) and its digital reconstruction (Di Vincenzo et al. 2017)

(*Homo sapiens*), in Africa, as well as to the Neanderthals (*Homo neanderthalensis*), in Europe, and the so-called Denisovans, in Northeastern Asia.

In conclusion, in view of the shape and morphological features displayed by Ceprano, it may be assumed that this specimen represents the best candidate available at present to describe the ancestral cranial morphology of the still largely unknown original variety of *Homo heidelbergensis* (Bruner and Manzi 2007; Mounier et al. 2011), which may be referred to as the stem chrono-subspecies of this taxon to be named *Homo heidelbergensis heidelbergensis* (Manzi 2016).

out brain stem

## Definition

The term cerebellum (Latin for a “small brain”) can be described as the miniature of the cerebrum. It is differentiated from the metencephalon during the fifth week of the fetal brain development (Ghosh et al. 2017; Kandel et al. 2000). It is the major subdivision of the hindbrain.

## Introduction

The cerebellum is a dorsally projecting region of the brain located at the base of the skull (Fig. 1). In an adult human being, the cerebellum weighs about 150 g and makes up to one-tenth of the total volume of the brain (Snell 2010).

It plays a major role as a unit of motor control for the body and contributes to its fine movement, precision, and time accuracy. The cerebellum is involved in some non-motor functions such as cognitive activities (language and attention) and in regulating pleasure and fear responses (Wolf et al. 2009). It is also associated with long-term synaptic depression (Purves et al. 2014) concerned with motor learning. It maintains the balance and posture of the body and coordinates movements (voluntary). Coordination of timing and forces of different muscle groups for body movement is one of the main cerebellar functions. It also aids in motor program adaptation and its fine-tuning for making accurate movements (Knierim 1997).

## Evolution

The cerebellar evolution is basically associated with the change in volume and surface folding (foliation) expansion across species. The initial role of the cerebellum was in motor control and is variously involved in a range of cognitive purposes including learning, memory, and language in humans (Hall et al. 2013). The presence of cerebellum-like structures in the non-vertebrates and cerebellum development in vertebrates suggests the existence of a common ancestor passed on as a homologous feature (a feature that is inherited from a common ancestor that also had the similar feature) (Bell et al. 2008).

## Evolution in Invertebrates

The cerebellum-like structures are responsible for the sensory inputs in invertebrates. These structures are thought to have been evolved into cerebellum. These structures are sensory in nature and receive inputs from peripheral deep layer and molecular layer parallel fibers.

In primitive chordates such as Myxinoidea and lampreys, there is no cerebellum. Parts of cerebellum-like structures called medial octavolateral nucleus (MON), dorsal octavolateral nucleus (DON), and Purkinje cells are responsible for information processing. DON and Purkinje cells are not present in Myxinoidea (Bell et al. 2008).

**Cerebellum,**

**Fig. 1** Lateral view of the human brain showing location of cerebellum (in gray)

**Evolution in Vertebrates**

Evolution from invertebrates to vertebrates has shown an increase in the cerebellar surface folding which in turn shows an increase in its neural processing or circuit and allows greater processing qualities and motor functions. A set of spinocerebellar tracts are involved to bring input to the cerebellum on body position and movements in all vertebrates. Termination of spinal tract is seen in the vermis and immediate adjacent cortex.

In most lower vertebrates (anamnia, cyclostomata), all classes of fishes, and most amphibians in place of a cerebellum, there exists an individual sensory system known as the lateral line, which is responsible for all seismosensory and mechanical movements (Kasumyan 2003). In birds, a small trace of cerebellar hemisphere is observed. The remaining part of the cerebellum is covered with vermis (Sultan and Glickstein 2007).

**Evolution in Mammals**

Anatomically, in humans and the higher primates, there are large cerebellar hemispheres with

upward and medial extension and complex folding of the cortex. Due to the extension of the hemisphere, there is almost complete covering of the vermis.

Input to the cerebellum in most humans and other mammals comes from the cerebral cortex through a relay in the pontine nuclei. Presence of flocculus (an essential lobe of cerebellum involved in the vestibulo-ocular reflex) is seen, which is responsible for motor control in all mammals and also in receiving input from the vestibular system and senses that signal the body's position in space (Sultan and Glickstein 2007). Different parts of brain involved during evolution in different organism is shown in Table 1 (Bell et al. 2008).

**Comparison Between Cerebellum-Like Structure and Cerebellum**

Granule cells, Golgi cells, unipolar brush cells, parallel fibers, stellate cells, and spine-covered molecular layer dendrites of principal cells are common in both of these structures. The two

inputs to cerebellum-like structures and the two inputs to cerebellar Purkinje cells present highlight the crucial similarity between them. Parallel fiber and peripheral input is received by the cerebellum-like structure while the parallel fiber input and climbing fiber input is received by the cerebellum through the Purkinje cells. One common characteristic between them is that the parallel fiber input conveys a variety of information to an entire principal cell set or to the Purkinje cells as the first input. Also as a second input, the peripheral input in cerebellum-like structure and the climbing fiber in the cerebellum relay specific information that subdivided the set of Purkinje cells that share the same parallel fiber input (Bell et al. 2008).

**Morphology**

The cerebellum consists of a massive white matter core covered by a cortical layer. The cerebellar nuclei buried in the white matter of the cerebellum receive their major input from the cerebellar cortex. Cerebellar output is then connected to structures in the thalamus and brain stem through the cells of the cerebellar nuclei. There are three lobes, an anterior lobe, a posterior lobe, and flocculonodular lobe, divided by two transverse fissures and small subdivisions in each lobe of the cortex called folia. Corpus cerebella, the main mass of the cerebellum, is formed by the anterior and posterior lobe together (Sultan and Glickstein 2007).

**Anatomy**

The cerebellum is located in the posterior cranial fossa behind pons and medulla. Tentorium cerebella (a layer of dura mater) separates the cerebellum

from pons and medulla. The fourth ventricle lies in between the cerebellum and the pons and medulla (Fig. 2). The cerebellum has an outer superficial layer in the gray matter known as the cerebellar cortex. This cortical region comprises a large number of parallel spaced grooves, which are predominantly composed of granule cells.

Beneath the cortical surface lies the white matter within which lie four deep cerebellar nuclei forming a tree-like structure called arbor vitae. Longitudinally, the cerebellum is divided into three parts, a vermis near the midline and two hemispheres surrounding the vermis from both sides. There are three peduncles in the cerebellum, which connects the cerebellum with the rest of the nervous system through several afferent and efferent fibers. The superior peduncle (brachium conjunctivum) connects to the cerebral cortex by carrying the efferent fibers to the upper motor neurons (UMNs). The middle peduncle (brachium pontis) receives inputs from pons relayed by the cerebral cortex. Inferior peduncle (restiform body) receives input from the spinal cord, vestibular nuclei, and the tegmentum. It also sends efferent fibers to the reticular formation and the vestibular nuclei.

**Division of Lobes in the Cerebellum**

The cerebellum is divided into three lobes by the two transverse fissures. The anterior lobe lies above the primary fissure and the posterior lobe just below it. The anterior and posterior lobe together forms the main mass of the cerebellum, also known as corpus cerebella. On the ventral surface, the flocculonodular lobe is separated by the rest of the cerebellum by the posterolateral fissure.

**Cerebellum, Fig. 2** Schematic representation of the subdivision of the cerebellum

#### Functional Classification of the Cerebellum

The cerebellum has three major divisions that have distinctive functions and connections: vestibulocerebellum, spinocerebellum, and cerebrocerebellum. The vestibulocerebellum is the oldest part of the cerebellum. It comprises the flocculonodular lobe and the lingual (most primitive part of the vermis). These receive visual and vestibular inputs and send them to the vestibular nuclei, participating in regulating body equilibrium and eye movements.

The spinocerebellum is also called as the paleocerebellum. It consists of the entire anterior lobe except the lingual. It receives proprioceptive and somatosensory inputs from the spinal cord and projects them to the cerebral cortex and brain stem. This region is concerned with maintaining the fine tune of the body and limb movements.

The most recently developed part of the cerebellum is the cerebrocerebellum. It consists of the lateral part of the hemisphere. Its input and output are connected to the cerebral cortex through pontine nuclei, which primarily participates in executing and planning voluntary movements. It has been reported that the cerebellum may also have a role in cognitive functions like working memory (Kandel et al. 2000).

#### Microcircuit of the Cerebellum

The entire gray matter of the cerebellum is arranged uniformly into three layers: granular layer, Purkinje layer, and molecular layer. These layers possess distinctive neurons, one efferent, and two afferent fibers and perform different functions.

##### Granular Layer

It is the innermost layer that rests on the white matter. It has about 100 million granule cells that make the layer looks densely packed. The layer also contains few Golgi interneurons, brush cells, and synaptic glomeruli. Granule cells are very small and numerous in number. The mossy fiber (one of the afferent fibers) terminates in the granular layer and synapses with short dendrites of granule cells in the synaptic complexes called cerebellar glomeruli. The axons of granule cells move to molecular layer and divide into parallel fibers (forming a T junction from each parent axon).

##### Purkinje Cell Layer

It is the middle layer consisting of the cell bodies of Purkinje cells. The dendrites of the Purkinje cells move vertically upward entering into the molecular layer. These dendrites receive input

from the afferent fibers and interneurons present in the molecular layer, while the axons of Purkinje cells extend downward into the white matter and synapses with the deep nuclei. Purkinje cells use GABA as a neurotransmitter and they are inhibitory to the deep nuclei.

### **Molecular Layer**

It is the outermost layer of the cerebellar cortex. They have two inhibitory interneurons: stellate cells and basket cells. They make connections with the parallel fibers of the granule cells and the extensively branched dendrites of Purkinje cells. Both are GABAergic and form inhibitory connections with Purkinje cells.

### **Afferent Fibers of the Cerebellum**

Mossy fibers arise from the cell bodies of the brain stem and spinal cord and terminate in the granular layer. They carry sensory information and form excitatory synapses with the dendrites of granule cells. Further, the axons of granule cells project the information to a large number of Purkinje cells.

Climbing fibers originated in the inferior olivary nucleus in the medulla. They carry sensory information and terminate in the molecular layer by passing the granular and Purkinje cells layers. Each climbing fiber climbs up to many Purkinje cells and synapses on them.

### **Efferent Fibers of the Cerebellum**

Efferent fibers are the axons of the Purkinje cells that project the information to the deep nuclei of the white matter. They are inhibitory to their targets. The flocculonodular lobe projects some efferent to the brain stem.

### **Deep Nuclei**

The core of the white matter has four cerebellar nuclei of gray matter: dentate, emboliform, globose, and fastigial. All the outputs of the cerebellar are from these cerebellar nuclei. These receive inhibitory inputs from the Purkinje cells and collateral inputs from the afferent fibers (mossy fibers and climbing fibers).

### **Connections of the Cerebellum**

The cerebellum has direct and indirect connections with the cerebral cortex and the spinal cord. Spinocerebellar pathways convey proprioceptive information to the cerebellum, which is responsible for maintaining body posture and controlling muscle tone. The cerebral cortex conveys information to cerebellum through centers present in the brain stem, such as the corticopontocerebellar pathway, cortico-olivocerebellar pathway, and corticoreticular cerebellar pathway. The cerebrocerebellar connections are concerned with the planning and execution of voluntary movements of the body. The cerebellum projects information to the thalamus, which then relays it to the cerebral cortex. The vestibular connection of the cerebellum through the semi-circular canals and the otolith organs helps in regulating balance and eye movements. The input from vestibular receptors and proprioceptors help make postural adjustments through the modulation of commands to motor neuron, which then compensates the shift in body movements or changing load of the muscles (Knierim 1997).

### **Cerebellar Dysfunctions**

Cerebellar dysfunctions are associated with ataxia (hereditary or acquired). Hereditary ataxia can be autosomal recessive (Friedreich ataxia, ataxia-telangiectasia, abetalipoproteinemia, ataxia with isolated vitamin E deficiency, and cerebrotendinous xanthomatosis) or autosomal dominant (spinocerebellar ataxia). Acquired ataxias involve neurodegenerative disorders, systemic disorders, multiple sclerosis, cerebellar strokes, repeated traumatic brain injury or toxin exposure or idiopathic reasons.

### **Disorders of the Cerebellum**

Cerebellar disorders can be diagnosed through clinical evaluation, MRI studies, and genetic testing and neuroimaging. The disorders are clinically diagnosed and a systemic disorder involves a

proper family history search. Treatment is usually supportive and sometimes involves surgery and treatment of the causal issues. The two major disorders are:

### 1. Cerebellar Motor Syndrome

The basic deficit common to the motor incapacity is impairment of rate, rhythm, and force of contraction. In the early stages of cerebellar degenerative disorders, balance is poor, and there is inability to stand on one leg or perform tandem gait. The patients show ataxia (impairment of gait), dysarthria (motor speech disorder), dysgraphia (difficulty in swallowing), hypotonia (low muscle tone), dysmetria (lack of coordinated movements), and dysdiadochokinesia (inability to perform rapid movements) (Schmahmann 2004).

### 2. Cerebellar Cognitive Affective Syndrome

This syndrome is characterized by difficulty in executive function (deficient planning, set-shifting, abstract reasoning, working memory, and decreased verbal fluency), impaired spatial cognition (including visual spatial disorganization and impaired visual-spatial memory), personality change (flattening or blunting of affect and disinhibited or inappropriate behavior), and linguistic difficulties (including dysprosodia, agrammatism, and mild anomia) (Schmahmann 2004).

## Cerebrotypes

Rie Henriksen and Dominic Wright  
AVIAN Behavioural Physiology and Genomics  
Group, IFM Biology, Linköping University,  
Linköping, Sweden

The vertebrate brain consists of distinct regions and subregions that differ in structural composition and functionality. Brain regions vary in size between species and population both in terms of absolute size and proportional size within the brain. These size differences are believed to reflect

differences in functionality with increased size providing more processing power, the hippocampus, for example, a brain region that is important for the formation of spatial memory tends to be larger in foodstoring birds than in nonfoodstoring birds (Clayton and Lee 1998). Cerebrotypes (*plural* cerebrotypes) refers to a specific type of brain composition that is shared between groups of animals. Most often, cerebrotypes are determined by dividing the volume of all major brain regions by the volume of the entire brain to create a series of volume fractions, which combine to make up an animal's cerebrotypes (Clark et al. 2001). This method allows a comparison of relative brain composition to be performed independent of total brain size and also takes into account that some brain regions are more anatomically and functionally linked than others resulting in correlated size evolution.

Cerebrotypes have been identified across a range of species, from mammals (Clark et al. 2001) and birds (Iwaniuk and Hurd 2005) to fish (Yopak 2012) and amphibians (Doré et al. 2002), with closely related species often sharing more similar cerebrotypes than more distant species. Multivariable analysis has revealed that some cerebrotypes cut across clades and can be related to a particular ecological or developmental niche shared by distant species. The extent to which cerebrotypes relate to phylogeny or ecology varies among species and lineages and therefore provides a useful tool for examining the evolution of brain composition in light of phylogeny, behavior, and ecology (Iwaniuk and Hurd 2005).

Cerebrotypes characteristics are not limited to the size of the major brain regions, but can affect many levels of brain anatomy. The patterns of gyrification (folding) of the cerebral cortex for example varies considerably between and within mammalian orders (Ventura-Antunes et al. 2013) and the number of neuronal and nonneuronal cells that make up the different brain regions have different neuronal scaling rules between orders. When comparing species, neuron number tends to increase with brain size, but often at a lower rate, resulting in a decrease in neuronal density with increasing brain size. Yet some orders, like

primates and parrots, are characterized by very high neuronal density, despite having relatively large brains. In parrots, for example, this is due to an exceptionally neuron-dense pallium, the brain region that is involved in higher cognitive processing in birds (Olkowicz et al. 2016). Similar to brain region size, these differences in brain region folding and neural density are believed to reflect both differences in processing power as well as phylogenetic constraints.

While cerebrotypes-based measures have mainly been used to look for interspecific variation, the method can also be used to compare brain compositions between populations of the same species. Intraspecific differences in brain composition between recently diverged populations have been identified in several species, but are especially well documented in domesticated species, where the domestication process has led to substantial changes in brain size and composition, resulting in domesticated animals having a different cerebrotypes than their wild progenitors (Kruska 2005; Henriksen et al. 2016). The advantage of interpopulation studies is that any difference in brain composition is more readily related to the environments in which the populations live and less confounded by changes in brain composition acquired at some point in the past and thus of little relation to the present environment, as can often be the case for interspecies studies. Therefore, although differences in cerebrotypes found within species may not be as extreme as those found between species, population comparisons within a single species can be used to associate brain composition with environmental or behavioral variation. Interpopulation differences have most notably been used to disentangle the genetic architecture underlying brain composition, mainly testing the independent (mosaic brain evolution) versus constraint (concerted brain evolution) hypothesis about brain composition evolution using quantitative genetics (Hager et al. 2012; Henriksen et al. 2016). The former hypothesis postulates that individual brain regions can develop and grow independently in size while the latter argues that different brain regions have been limited by developmental constraints and that the brain alters predominantly as a whole.

In summary, the term cerebrotypes has a broad definition and application. It can be used to characterize and distinguish brain composition at different anatomical levels, from neuronal density to brain regions size and it can be used to compare animals of the same species or from distinct species to answer ultimate questions about the evolution and functionality of brain composition as well as disentangle the underlying mechanism that underlies variation in brain composition between animals.

## Evolutionary Origin of Grieving Among Mammals

Behavioral patterns and psychological dispositions toward the dead – including grieving, mourning, and bereavement – have been studied thoroughly among humans, but similar behaviors are poorly understood when performed by non-human mammals. The shared roots of grieving among humans and other animals were recognized early by Charles Darwin (1872) and the evolutionary meaning and significance of grieving were later elaborated in the work of authors such as John Archer, John Bowlby, and Colin M. Parkes. Their insightful writings explain that grief is ultimately a reaction to a deficit, arising as a by-product of the broadly similar reaction to separation. In other words, grieving is the cost of commitment (Parkes 1972), the downside of attachment and love (Archer 1999), and its emotional responses have evolved from the basic need of maintaining proximity with a partner or offspring. The maladaptive aspects of grieving have been seen as a trade-off with other adaptive

features, needed to maintain a stable relationship. Grieving results from the breaking of attachment bonds and its intensity generally parallels the strength of attachment: as Archer states, “if there is no attachment, there will be no grief.” When a dear one dies, the longing remains largely intact and the experience of loss often produces responses including distress, depression, and compulsive behaviors that may ultimately threaten the survivor, as documented by studies of humans and by a limited number of studies on other mammals (particularly primates).

While understanding death is generally regarded as a human attribute, such understanding *per se* does not necessarily help us overcome behavioral patterns and emotional responses that are deeply rooted in our evolutionary history. Observations of cetaceans (the taxonomic group that includes whales, dolphins and porpoises) suggest that at least in some cases – most notably upon the death of an offspring – behavioral patterns and emotional responses can parallel those found among humans and other terrestrial mammals. Whether or not they are explicitly referred to as grieving, cetacean reactions to a loss can be behaviorally extreme, strikingly maladaptive, and long-lasting. Such reactions possibly reflect aspects of bereavement, generated by terminal breaking of the strong social bonds known to exist among some cetacean species.

## Epimeletic Behavior

The term “epimeletic” (but also “caregiving,” “supporting,” “nurturant,” and “succourant”) has been employed with reference to cetacean behavior toward the dead or dying. The term is a catch-all to characterize a range of behavioral patterns encompassing rescue and resuscitation attempts, postmortem bereavement, the use of surrogates, and compulsive stereotypic behavior (Bearzi and Reggente 2017). Epimeletic behavior (Fig. 1) typically refers to one or more individuals who consistently stay near an injured or dead one, maintaining physical contact, lifting or keeping it afloat, and moving or carrying it along. If the dead individual is taken away by observers, or

**Cetacean Behavior Toward the Dead and Dying, Fig. 1** An adult striped dolphin *Stenella coeruleoalba* of unknown sex performing “epimeletic behavior” toward a dead conspecific (a subadult female) in the Gulf of Corinth, Greece (Photo by Silvia Bonizzoni/Dolphin Biology and Conservation)

approached by predators, the caregivers may behave aggressively or defensively. If a cetacean naturally strands, caregivers may remain in the area for some time and potentially risk stranding themselves. Epimeletic behavior involves other maladaptive aspects such as prolonged contact with a decomposed and potentially diseased carcass. While epimeletic behavior typically refers to a healthy adult caring for an impaired or dead individual (often a calf), the term is sometimes used with reference to behaviors that may not have truly epimeletic (i.e., altruistic) components.

## Cases of Epimeletic Behavior

Possibly more than one hundred cases related to epimeletic behavior have been documented in captive or free-ranging cetaceans (Norris and Prescott 1961; Caldwell and Caldwell 1966; Reggente et al. 2016), but reports tend to be opportunistic with an anecdotal, descriptive, and nonexperimental character. Early reports tend to be particularly blurry and most pre-1970 cases refer to either animals killed by whalers, observations resulting from the deliberate harming and killing of animals “for science,” or cetaceans held in captivity, not ideal settings for unbiased observations of natural behavior. The discussion

in this entry refers to post-1970 published literature of cetacean behavior in the wild.

Cetaceans include 89 extant species, but the published reports of epimeletic behavior are restricted to a much smaller subset of relatively well-studied species. Of 45 published reports of cetacean behavior toward dead or dying conspecifics, 24 (53%) refer to only two genera: *Tursiops* (17 cases) and *Globicephala* (7). The remaining reports are scattered across 12 other genera, all within the family Delphinidae except for two cases involving the beluga *Delphinapterus leucas*, one involving the sperm whale *Physeter macrocephalus* and one involving the humpback whale *Megaptera novaeangliae*. The number of reports per species depends in part on opportunities of observing a relatively rare behavior, which vary depending on species abundance, distribution (e.g., increased accessibility due to proximity to shore), and other factors. Even considering these factors, cases of caregiving behavior appear rare among mysticetes (most cases are dated whaling episodes where individuals reacted to harpooned calves or group members; Caldwell and Caldwell 1966). Cases also appear to be uncommon among some intensively studied odontocetes. For instance, only one published record of epimeletic behavior exists for the highly social and cognitively advanced killer whale *Orcinus orca* (the observation of a female carrying a dead neonate in her mouth; Reggente et al. 2016).

Apart from the differences among species (cetaceans differ greatly in body size, cephalization, ecology, behavior, and social organization), differences are likely to exist within species. Attitudes towards the dead are known to have remarkable individual and cultural variability among human and nonhuman animals alike (Archer 1999; King 2013). Variability within the same cetacean species, or even within populations or groups of conspecifics may occur, due to differences related to age, sex, relationship with the deceased, ecological context, predation risk, and a number of other nontaxonomic factors. Because of the small sample size and other sampling constraints, the known cases of cetacean behavior toward the dead or dying may not represent the “typical” repertory of a particular species.

## Caregivers and Receivers

Among humans, grief parallels the strength of attachment between caregiver and receiver, and the loss of a child is regarded as the most difficult to bear. Mothers generally show higher levels of attachment than fathers, because females make the greatest parental investment and paternity among males is uncertain (Archer 1999). Consistent with studies of wild terrestrial mammals, the caregiver among cetaceans is invariably an adult and the receiver is mostly a dead calf or juvenile (89% of 45 events directed toward conspecifics). When cases involve dead calves and the sex of the caregiver is known ( $n=12$ ), it is typically a female (92%). Published observations of known male caregivers are limited to the single case of an adult short-finned pilot whale *G. macrorhynchus* carrying a dead calf in his mouth while swimming among other group members (Baird 2016). While this behavior was interpreted as grieving by the author, it may have alternative explanations. For instance, cases of infanticide and violent aggression directed toward conspecifics (and nonconspecifics) are not uncommon among common bottlenose dolphins *T. truncatus* and have been reported to occur in several other cetacean species. Considering these cases, it cannot be ruled out that a male may be carrying a dead calf – that he might have killed himself – to ensure the calf’s mother stays with him (possibly resulting in reproductive benefits when the time comes), as a “trophy,” or for other unknown reasons (Shane 1994).

Female caregivers are often inferred to be the mothers of the dead or dying calf, but parenthood is rarely confirmed. In one well-documented case, an unrelated female was observed providing most of the care to another female’s dead calf (Quintana-Rizzo and Wells 2016). A related observation involved a bottlenose dolphin mother who spent considerably more time with her grandson following the death of her own calf (Mann and Barnett 1999), possibly as a form of “compensation.”

In approximately 10% of the published observations from the wild, the main caregiver is assisted by other individuals, sometimes called

“escorts,” which actively help support a dead or dying calf at the surface by pushing or nudging the carcass. Compared to these observations involving dead calves, records of multiple individuals targeting a dead adult or subadult conspecific (five observations, 11% of the total) appear to belong to a different category of behavior. All of the five observations include instances of arousal such as belly-to-belly contact, erected penises, and mating attempts targeting the deceased. Conversely, no cases of arousal have ever been observed among escorting group members when the receiver is a dead calf. Cases of necrophilia with dead conspecifics, and non-conspecifics alike, have been observed among wild marine mammal males (Harris et al. 2010), but these behaviors are rare in most mammalian species. Among cetaceans, cases of arousal in the presence of a dead adult or subadult conspecific seem to be common when several group members are present. In one of the five observations, the dead target was a subadult male bottlenose dolphin (Dudzinski et al. 2003); in another, an adult male humpback whale that was killed during a competitive interaction with conspecifics (Pack et al. 1998). Sexual arousal may be triggered by physiological responses related to stress or be expressions of dominance, devoid of a reproductive purpose.

### Learning to Mother

The hypothesis known as “learning to mother” has been proposed to explain the carrying of dead offspring by nonhuman primates (e.g., Warren and Williamson 2004). This hypothesis contends that benefits can be gained by carrying a corpse, for instance, to learn useful motor skills while traveling and foraging. Because even brief exposure to infants can improve maternal skills among primates, it has been conjectured that carrying a dead infant may make a mother more capable of dealing with subsequent offspring that need to be carried. Practicing of parental skills also has been proposed to explain epimeletic behavior and carrying of dead calves by cetaceans, though none of the extant cetacean species

would “carry” their living calves, and the benefits of practicing such behavior are dubious.

### Resuscitation Attempts

Grieving can reduce the survival of the caregiver due to energy expenditure, stress, increased exposure to predation risk, lower foraging opportunities, and other factors. The reactions of caregivers, however, can potentially have an adaptive component. While no inference can be made as to whether the caregiver knows that the receiver is alive or dead, observations of terrestrial mammals suggest that an inanimate receiver can return to life following forceful manipulation, hits, and strokes by a caregiver. Protracted manipulation of an inanimate body may be the animal equivalent of cardiopulmonary resuscitation. The typically energy-expensive initial phases of grieving, involving a “denial of reality” (Archer 1999), and active or even aggressive behavior may therefore have the occasional benefit of rescuing an apparently dead individual.

Cetacean mothers are known to respond to nonbreathing newborns by lifting them to the surface and stimulating the first breath, arguably an evolutionarily important behavior which general pattern might be related to similar attempts following perinatal death (Krasnova et al. 2014). Whether or not persistent manipulation actually results in occasional resuscitation among inanimate cetaceans is not known, but this possibility cannot be ruled out. Among cetaceans, however, such behavior is not limited to the time immediately following death, as one would expect if handling was exclusively related to resuscitation attempts having any chance of success. For instance, forceful handling involving tossing and vigorous strikes has included calves and juvenile cetaceans in moderate decomposition.

### Length of Carry and Phases of Grief

Whether or not the caregivers can discriminate between life and death, or have an understanding

thereof, proximity with the deceased facilitates acceptance of death, or at least can contribute to the necessary behavioral and emotional transitions. Among humans, there is a consensus that it is helpful for parents to see or hold their baby following a stillbirth. Human mothers need a period of time to come to terms with the loss, and maintaining proximity with a dead baby may help mitigate the trauma of separation. In such a context, grieving may have therapeutic benefits (Archer 1999). A cetacean corollary is that the well-intentioned decision of taking dead calves away from caregiving dolphins – often reported in the published literature (29% of the sample) – may not be in the best interest of the surviving animal(s), particularly in the early phases of grieving and following perinatal death.

In later phases, attachment and social bonds represent powerful psychological mechanisms delaying abandonment and the caregiver may become incapable of letting go. Unwillingness to leave the dead may prompt behaviors to become compulsive and stereotypic, with an increase in apparently maladaptive and aberrant components. Several odontocete species have been observed carrying calves in advanced decomposition, sometimes flaccid remains beyond recognition or even body parts (e.g., a truncated head). Only a few mammal species, all of which are primates, are known to carry the dead as long as cetaceans. Primate mothers of several species can carry their dead infants for days or weeks before abandoning them, sometimes until they are mummified – a behavior that has been related to extreme climatic conditions slowing down decomposition and extending the periods over which dead infants can be carried (Fashing et al. 2011).

Cetaceans can carry a dead calf over long distances while swimming and diving. Facilitated by reduced gravity, these aquatic mammals can afford carrying dead bodies for long periods of time, and some foraging obviously must occur when the carrying is protracted for weeks. Odontocete species with a dorsal fin may find it easier to carry a dead calf on their dorsum, draped over the anterior edge of their fin, while continuing to move and forage. Carrying may be

comparatively more costly for deep-diving cetaceans or fast-moving gregarious species. For most terrestrial mammals, transporting a dead body can be challenging, or even virtually impossible. For example, giraffe mothers *Giraffa* sp. can remain vigilant in proximity to their dead calf for periods up to several days (Bercovitch 2013), but would not be able to actually carry it. Ring-tailed lemurs *Lemur catta* can hardly carry infants that do not hold themselves to their fur, and have been documented moving between a dead infant and their troop (Nakamichi et al. 1996). A comparatively lower energetic cost of carrying, for at least some cetacean species, may contribute to delayed abandonment as compared to other taxa. An additional factor that might delay abandonment of a decomposing carcass is the apparent lack of olfaction and taste in most cetaceans (Cozzi et al. 2017), which could potentially result in weak avoidance mechanisms. In terrestrial mammals with a pronounced olfaction, decomposition processes and the smell of death likely deter proximity to decaying bodies, implying a risk of disease transmission that triggers avoidance as decomposition progresses.

What causes a female to eventually stop carrying a dead calf? Among primates, physiological changes in the mother associated with infant death have been suggested to play a role in the abandonment. For instance, postpartum amenorrhea is shortened after an infant's death, and the hormonal changes preparing the mother for the arrival of a new infant may contribute to a gradual release of the attachment to the dead infant and its remains (Biro et al. 2010). Among human mothers, the absence or cessation of breastfeeding may increase the desire to hold their baby, but such a desire will tend to fade over time. Similar physiological and psychological changes mediated by hormonal shifts are likely to occur among cetaceans as well, creating the conditions for abandonment. Other factors that may contribute to promoting detachment from the dead include the risk of losing contact with other group members when the rest of the group moves away, fear or uneasiness resulting from isolation and increased predation risk, and hunger.

## Surrogates and Other Species

While caring for a living conspecific is clearly adaptive (Clutton-Brock 2009), the evolutionary meaning of caring becomes blurred when targets are living individuals or carcasses of other species, or even objects. In some of these cases, non-conspecifics and objects may become surrogates that help mitigate separation distress and address an overwhelming need to maintain attachment, if merely an illusion thereof. Even in these cases, the caregiver may respond in a protective manner when observers attempt to approach or remove their burden – whether unrelated animals or objects.

A vivid example – though not necessarily representative of natural behavior – is given by a captive beluga whose dead calf was removed from the pool postpartum. The female first started carrying her own placenta, and after the placenta was removed she resorted to a buoy, which she continued carrying for several months (Kilborn 1994). Possibly related observations (for a total of seven occurrences) were made in the wild, where belugas of undetermined sex were reported carrying a newborn, a placenta and amniotic sac, a piece of seine net, planks up to 2–2.5 m long (four cases), and the entire skeleton of a dead caribou *Rangifer tarandus* (Smith and Sleno 1986). These short-lasting and nonsystematic observations could document a need for surrogates following the death of previous calves, similar to the case observed in captivity, though some cases may have different meanings, such as playful behavior.

A particularly puzzling series of observations involved several short-finned pilot whales persistently carrying dead California sea lions *Zalophus californianus* in various stages of decomposition (“from freshly dead to furless blubbery corpses with bones extruding”; Shane 1994). This behavior was performed consistently by several pilot whales in 19 separate events observed over 12 days, with only two cases attributed to adult males. Considering the lack of social bonds between pilot whales and sea lions and several other aspects inconsistent with the hypothesis of epimeletic behavior or grieving, these events were tentatively explained as a way of conferring a particular status to the carrier (Shane 1994).

However, the interpretation of these and other cases involving the carrying of dead non-conspecifics remains largely conjectural.

Cases of nonoffspring “adoption” and care toward living nonconspecifics are not uncommon among cetaceans and other mammals and may represent practice to deal skillfully with one’s own offspring. Caregiving behaviors directed toward living and dead nonconspecifics may also express (and potentially reinforce) “compassionate” behaviors that – beyond being apparently misdirected byproducts of generally adaptive models – can yield long-term net benefits. Such behaviors may include unexpected targets, adding striking aspects to the vast cetacean repertory. For instance, “interspecific altruism” was postulated to explain the repeatedly observed mobbing of mammal-eating killer whales by humpback whales, apparently intended to protect other cetacean species, but also pinnipeds and even a fish (the ocean sunfish *Mola mola*; Pitman et al. 2017).

## Neural Basis of Grieving

What is the neural basis behind the complex behavior shown by some cetacean species towards the dead and dying, and is such a neural basis shared by all mammals displaying similar behaviors? “Higher” emotional behavior in humans and other primates has been at least partially localized in the orbitofrontal cortex, and instinctive behavior may be organized and activated by sensory areas, by the cingulate cortex and the amygdala (Rolls 2011). These parts, and their connections, may be identified and compared in different species by certain anatomical boundaries, but especially by their structure (i.e., the way the neurons that constitute them are placed, connected, and communicate chemically).

The functional anatomy of the cetacean brain has been particularly well studied in the common bottlenose dolphin (Cozzi et al. 2017). The structure and functional organization of the neocortex of this species disclose a thinner cortex and a different, apparently less complex, circuitry. The human neocortex (but also that of rodents and terrestrial carnivores), including the orbitofrontal,

is a six-layered structure in which the fourth layer from the top plays a pivotal role and appears prominent in the brain's sensory and associative areas. Among cetaceans, the fourth layer is absent or extremely reduced (Hof et al. 1999), and the projections of the cortex from and to the rest of the brain must follow a different pathway, with a circuitry similar to that of hoofed mammals (Cozzi et al. 2017).

An analysis of cetaceans' limbic lobe leads to similar conclusions: a large part of the components of the limbic lobe in terrestrial mammals are phylogenetically and physiologically linked to the olfactory lobes and the perception of smell. Odontocetes have no olfactory nerve and lack all of the connected structures (Cozzi et al. 2017). Mysticetes have remnants of the olfactory structures, but their functionality remains to be validated. All that is left of the limbic lobe in cetaceans is an extremely reduced hippocampus (Morgane et al. 1982), so small that it may be difficult to identify even in very large brains (as a comparison, the same structure may amount to 1/5 or 1/6 of the entire telencephalon in some hoofed mammals).

The neuroanatomical aspects summarized above suggest that the structures of the dolphin brain potentially (by comparison) involved in emotional and instinctive behavior follow a strikingly different organization compared to humans and other terrestrial mammals: they have fewer neural layers, alternative neurochemical communication, and relatively simpler circuitry. Therefore, the grieving behavior of dolphins and that of humans and other well-studied terrestrial mammals cannot be based on comparable neuroanatomical and neurophysiological patterns. Observations of caregiving dolphins reviewed in this entry may lead to psychological analogies that remain unexplained by our current understanding of the structures physiologically involved in the neural basis of such behavior.

## Conclusion

Beyond the remarkable differences in neuroanatomy, we concur with Darwin that if related species

show similar responses under similar circumstances, the underlying proximate processes are probably homologous (i.e., derived from a common ancestor) rather than analogous (i.e., independently evolved) – a view consistent with recent research on mammalian empathy (de Waal and Preston 2017). A wide variety of vertebrates showing social attachment and parental care have a motivation to help distressed and vulnerable targets (de Waal and Preston 2017), and reactions equivalent to human grief can be expected among social animals separated by a companion with whom they have an evolutionarily important prolonged relationship (Archer 1999). Field observations of odontocetes suggest neural perception-action mechanisms similar to those observed among social terrestrial mammals such as primates – particularly when an adult female and a dead calf are involved. Nevertheless, several other aspects of cetacean behavior toward the dead and dying remain obscure, particularly when the target is a dead adult conspecific, or a dead nonconspecific. Clearly, much remains to be done to achieve a satisfactory understanding of the cognitive and behavioral aspects surrounding death among cetaceans.

Occurrence of caregiving behavior among different cetacean species deserves to be better investigated and framed in the larger context of research on behavioral patterns that may be expressions of empathy in nonhuman vertebrates.

## Synonyms

Dolphin; Thinking; Whale

## Definition

Cetacean cognition concerns thinking mechanisms like perception, memory, and forms of communication in dolphins and whales. Cetaceans are divided into two suborders: odontocetes (toothed dolphins and whales) and mysticetes (baleen whales).

## Introduction

Cetaceans' ancestors were land mammals, but the first “whales” appeared a very long time ago – more than 50 million years in the past – and adaptation to aquatic life occurred slowly over the millennia. Not only did those adaptations include shifts like the movement of the “nostrils” from the front to the top of the head (today’s “blowhole”), but they also led to changes in systems critical to cognition like sensory and perceptual processes and the structure of the brain, which

in turn coevolved with effective behaviors for life in the water. Here we discuss some of those processes and behaviors with specific focus on perception, communication, social learning, learning and memory, and other approaches to the study of cognition. (For recent reviews, see Herzing and Johnson 2015.) Because the study of cognitive mechanisms typically requires controlled studies, most of this entry is based on data with small odontocetes, particularly the robust bottlenose dolphin (*Tursiops truncatus* or *Tursiops aduncus*). (For reviews from many marine mammal laboratories, see two issues of the *International Journal of Comparative Psychology*, 2010, edited by Kuczaj.) However, on occasion other odontocetes are also included as well as a section on the complex and cognitively interesting songs of the humpback whale, a mysticete.

Most experimental research on dolphin cognition and sensory studies in captive settings are based on studies of only a few subjects, frequently only one. Replication studies by different researchers at other laboratories are rare. It is assumed that cognitive attributes, usually to questions concerning “can a dolphin do X?”, displayed by any single dolphin are shared by others. Observational protocols in captive or, more often, in natural settings usually involve larger sample sizes but lack the controls to definitively determine cognitive processes.

## Echolocation and the dolphin's Perceptual World

Sound travels very efficiently in water – more than four times faster than in air – and cetaceans take advantage of that fact. Their perceptual world is strongly influenced by sound; however, perception of other kinds of energy is also important to dolphins. Their visual systems are well developed for underwater and aerial viewing. Underwater visual acuity is about 8 arc minutes and in air 12.5 arc minutes, good vision for non-primates but in the vicinity of “legal blindness” for humans. Dolphins are monochromats, suggesting that they would not have color vision. Nevertheless, there is some experimental evidence that they might be

able to discriminate color through rod/cone interactions. Much less is known about tactile perception, although morphological and evoked potential studies indicate somatic sensitivity, especially rostrally, which might be useful in monitoring water flow. Olfactory bulbs are absent in odontocetes which suggests an absent or weak sense of smell. Investigations of the anatomy of the dolphin tongue indicate reduced receptor development, although a limited number of psychophysical studies suggest good sensitivity for some tastes. Anatomical and correlational evidence based on locations of live stranding sites and migration routes in odontocetes and mysticetes suggests that they might navigate using magnetic detection. (See reviews of perceptual systems in Supin et al. 2001; Thewissen and Nummela 2008; Wartzok and Ketten 1999.)

A great deal about what a dolphin knows about its environment comes from sound. For example, odontocetes investigate their world through their ability to echolocate. To echolocate, the dolphin produces click sounds within the nasal passages underneath its blowhole, the opening at the top of the head through which the dolphin breathes. The very short (40–70  $\mu$ sec), very loud (180–225 dB re 1  $\mu$ Pa at 1 m) click is directed through the viscous “acoustic fat” in the dolphin’s melon (the bulbous front of its head) in a narrow beam of sound that bounces off objects in the environment and returns to the dolphin in the form of an echo, which is received primarily through the lower jaw. (See Au 1993, and Surlykke et al. 2014 for reviews.) Dolphins usually send out a click and wait for its returning echo before sending out another click, likely in order to process the echo in terms of the attributes of the click, although they may produce packets of clicks when targets are distant. Because echoic object investigation can happen in seconds or less, the dolphin’s click train usually sounds like a buzz to the human ear but would be perceived differently by a dolphin because dolphins process sound so quickly. Sounds that occur more than 264  $\mu$ sec apart are heard as separate sounds by a dolphin.

Dolphins can control their click trains to get more information about the objects in their environment. They hear across a very broad frequency

range, beyond 120 kHz (compared to humans’ 20 kHz upper limit), and so have effective options for creating a good signal within noisy conditions. For example, dolphins can produce high-frequency clicks to avoid low-frequency noise, more clicks, and louder clicks in order to get echoes that are easier to decode. The dolphin’s brain is built for processing sound. For example, the inferior colliculus, important for hearing, is 40 times larger in dolphins than in humans even though these two species’ brains are similar in size. Dolphins likely represent acoustic information in great detail.

Although we do not know exactly how dolphins recognize objects using echoes, we do know some of the echoes’ attributes that might help. (See Harley and DeLong 2008, for a review.) For objects that vary only in size, like different-sized disks, dolphins can use differences in amplitude to discriminate among the disks. For objects that vary only in material, like an aluminum versus a stainless steel cylinder, dolphins may use different pitches to tell the objects apart. Once objects get more complex and vary across many features simultaneously, it is more difficult to know how the dolphins manage recognition tasks because echoes from different attributes interact. For example, echoes returning from different angles of the same object can sometimes vary more than echoes from different objects vary. At present, no man-made sonar system is nearly as effective as a dolphin’s biosonar system in terms of object recognition.

Echoic object recognition is more than a sound-matching task (Harley and DeLong 2008). Dolphins can recognize an equivalence between the features of an object that they see and the features of an object that they detect through echolocation alone as evidenced by their ability to match unfamiliar objects across modalities: They can see an object in air where they cannot echolocate (the density differences between air and water are too great for dolphins to echolocate in air) and then recognize that same object again when it is presented behind a visually opaque but echoically transparent screen underwater. They can also integrate visual and echoic information: Visual information can disambiguate objects that are similar echoically and vice versa; in such

situations, dolphins are better at object recognition when they can simultaneously get visual and echoic information at the same time. These findings indicate that dolphins organize their information about objects around objects because they use information about how an object looks and how it sounds within a single representation of that object.

A non-echolocating dolphin can also get enough information to recognize some objects when it is simply listening to the returning echoes of a very close neighbor who is echolocating. Hence, dolphins swimming closely together can likely determine with some specificity to which aspects of the environment a close neighbor is attending. This ability to attend jointly to an object suggests that dolphins likely use echolocation as a method for cooperation and communication.

## Communication

Although echolocation is usually considered a method of investigating the world, its accessibility to other listening dolphins makes it likely that it is also part of the dolphin's communication system. Other vocalizations on which we know dolphins rely for communication are whistles and burst-pulse sounds. (See Harley 2008, and Janik 2009, for reviews on communication.) Burst-pulse sounds are broadband sounds (include many frequencies at once) that are essentially echolocation clicks produced at a very high rate. These sounds are often associated with socially intense encounters like group feeding or conflict situations. Although most of the energy in these sounds often occurs above the human hearing range (above 20 kHz), humans do hear the lower-frequency components of these vocalizations and describe them as squawks, blats, mewings, raspberries, brays, and more. Our ignorance of the dolphin's perception and use of burst-pulse sounds invites more study.

Whistles appear to be central to communication for many odontocetes. Whistles can occur at many frequencies, but they often have a fundamental frequency between 5 and 15 kHz, accessible to human hearing, with high-frequency

harmonics. The most well studied of dolphins' whistles is the signature whistle, a typically long and repeated whistle that appears to serve as an individual identifier in order to maintain group cohesion. Each dolphin's signature whistle has a unique frequency contour such that the pitch changes in a specific way over time, e.g., it may move from 5 kHz to 8 kHz to 5 kHz and then slowly rise to 6 kHz across a second of time. Dolphins can tell these whistles apart and associate them with specific producers. Dolphins also can and do imitate each other's whistles. Although signature whistles tend to be stable after their initial development in the first year of a dolphin calf's life, the whistles of older animals that spend a great deal of time together sometimes reflect influences of the signature whistles of their close associates.

Dolphins can produce both the narrowband whistles and the broadband pulses simultaneously, although the functions of these dual emissions are unknown. Vocal productions can be very rich and complex in that there is a ratio of repetition and variability sometimes associated with information transfer. At present, however, most of the dolphin's sounds remain indecipherable to us.

We do know that dolphins can glean information from sequences. Dolphins in human care have learned to respond differentially to sounds and human gestures presented in different orders. For example, when the dolphin Akeakamai at Louis Herman's lab in Hawaii saw gestures associated with specific items and actions, she responded differently depending upon the orders of the gestures: *Frisbee Ball Fetch* (IndirectObject DirectObject Verb) led her to bring the ball to the Frisbee, whereas *Ball Frisbee Fetch* led her to bring the Frisbee to the ball. Her sensitivity to sequence was so powerful that she could respond appropriately to new commands she had never experienced based on her understanding of the placement of items in a sequence, e.g., she could treat an item as an indirect object because of its position in the string of gestures. Further work with the same animal indicated that she could respond flexibly within this human-directed communication system on many counts: She could respond appropriately to queries about the presence and

absence of objects, identify objects based on location, respond to commands conveyed via video screen, interpret anomalous commands systematically, learn to respond with specific body parts in novel ways, and more. Another dolphin in the same lab confirmed good sequence processing when she learned to categorize melodies as going up or down even when they had been shifted to new tones. Related to sequence, dolphins can recognize relative number magnitudes in an ordered series when the size of the objects and background area is controlled. For example, when all pairwise comparisons between 1 and 8 differentially sized circles are tested, the subjects correctly select the lesser number. (See Pack 2015, for a recent review of laboratory work with dolphins.)

Dolphins can also be trained to respond appropriately to pointing gestures presented by humans (including direct and cross-body pointing), and they can point themselves to communicate with humans. In one study, dolphins swam in a pool in which there were fish within jars, and they began to spontaneously indicate the presence of a jar when they found one. In these cases, the dolphin would point his rostrum (bottlenose) toward the jar, often turn his head toward a trainer swimming toward him as though monitoring the human, and then turn his head back to the jar. The presence of the person was important to the behavior; the dolphins never pointed when a human was not in the water and rarely pointed when a trainer was in the water but behind a barrier.

### Social Learning in the Laboratory

As their communicative behaviors suggest, dolphins are socially capable and are good at learning from others. Not only do dolphins imitate each other's signature whistles, but dolphins in human care have also spontaneously imitated trainers' whistles, computer-generated tones, both fundamentals and harmonics, and a pulsed sound. (See Harley 2008, for a review.) To demonstrate a concept of sound mimicry, imitation was brought under stimulus control when a single dolphin was presented with a model sound followed by a signal "to mimic" and rewarded when she matched the model.

Vocal behaviors are not the only behaviors learned socially. Initially, the ability of cetaceans to imitate, a cognitively sophisticated form of social learning, was suggested by frequent observations of synchronous behavior in the wild, usually swimming, respiration, or leaping behavior seen as dolphins traveled at the surface. (See Herman 2002, and Whitehead and Rendell 2015, for reviews of social learning.) Synchrony is one of the earliest behaviors seen during ontogeny by bottlenose dolphins, beginning shortly after birth, and may be the basis for their powerful social learning abilities (Fellner et al. 2012).

Anecdotal evidence of observational learning was also provided in examples from commercial cetacean shows. A false killer whale learned without training the show behaviors of a pilot whale, and two rough-toothed dolphins produced each other's routines, for which they had not been trained. A bottlenose dolphin copied within minutes the unique jumping behavior of a spinner dolphin, *Stenella longirostris*, newly introduced to its tank even though bottlenose dolphins do not normally exhibit this type of spinning jump. Dolphins even mimicked non-cetaceans including fur seals and humans, e.g., cleaning the algae for port windows in their tank with a seagull feather and other objects while making noises and releasing bubbles of air like the scuba divers who cleaned the underwater windows and, in another example, a nursing calf releasing a cloud of milk toward an underwater window in response to a visitor smoking a cigarette and blowing a cloud of smoke.

Controlled experimental studies have supported these informal observations. Young dolphins trained to do the same behavior as a human model successfully mimicked a wide variety of species typical and novel behaviors like blowing bubbles and putting an object in a basket. Similarly, dolphins learned to respond to a specific hand sign that indicated an imitator should perform the behavior of a model dolphin, live or via television screen, even after a delay. Blindfolded dolphins can imitate behaviors based on acoustic or possibly tactile cues. Dolphins can also perform behaviors synchronously when only one of the pair knows the behavior to be produced:

A companion dolphin was able to perform simultaneous behaviors with another dolphin that alone had seen a hand sign indicating the required behavior. Video analysis indicated there were trials with no apparent leader but with a short delay, suggesting some type of preparation. Although most studies revealed powerful imitative abilities, imitation does not always occur readily; differences in training history, age, dominant-subordinate relationships, or other factors may affect imitation.

Altogether, this laboratory evidence indicates that dolphin's observational learning behavior is a clear cognitive strength. Dolphins can imitate the behavior of other species including humans. They are facile at imitating in both the vocal and motor domains, a characteristic apparently rare among mammals, although reported in birds. Mimetic behavior is displayed spontaneously and under experimental stimulus control, both synchronously and after delays, which indicates at least some short-term stability of behavioral representation. The ability to mimic on command suggests that dolphins have a concept of mimicry a concept even robust enough to be displayed in response to dolphin and human actions presented on a television screen.

Studies in the laboratory allow demonstration of dolphin's mimetic capabilities, but they do not show how mimesis might be used in the wild. Alternatively, research in natural settings can show how mimicry can be used in the wild, but they usually do not allow for the controls necessary to exclude other explanations for similarity of behavior, such as ecological pressure and genetic causation. Nevertheless, careful analysis reveals that a variety of behaviors observed in the wild likely emerged through social learning.

## Social Learning in the Wild

The baleen whales (mysticetes) engage in a variety of behaviors that suggest complex cognition (vocalizations, cooperative feeding, memory for migratory destinations) but the lack of controlled studies makes it difficult in most cases to separate tightly genetically controlled systems from

learned behaviors. Humpback whale song, however, is an exception where evidence indicates that learning processes are important in the production of structured and changing vocal displays. (For reviews of humpback whale song, see Payne 1983, and Whitehead and Rendell 2015.)

Humpback whales migrate between polar regions, where they feed during summers, and tropical waters, where they calve and mate during winter months. In tropical waters, males sing an elaborate song at frequencies between about 30 Hz and 4 kHz. The songs are hierarchically structured with themes comprised of phrases and phrases comprised of units. Songs generally have fewer than ten themes, but for any one song, the number and order of themes are fixed. The major area of flexibility in a song is the number of phrases in a theme, but the themes are always presented in the same order. When the sequence of themes is finished, the song is repeated, usually without pause. Repetitions may last for hours. The length of a song may vary, generally between 10 and 30 min, depending on the number of phrases in a song and the length of units within phrases. The units of a song may last from 0.15 s to 8 s and include tonal whistles and broadband sounds of varying complexity.

Humpback whales are found in discrete populations where exchange of individuals is unusual. All the humpback whales in a population sing the same song. The song changes over the course of a season and between seasons for the group by changing, adding, or dropping themes, a characteristic that is consistent with vocal learning. More evidence that the songs are learned is provided by the pattern of transmission. South Pacific songs move from east to west, while at the same time there is very little actual east-west movement by individual whales. Therefore, the changes in song in a population do not represent a movement of individuals singing the same song; it represents movement of information.

To learn, remember, and produce complex, changing songs would appear to place substantial cognitive demands on male humpbacks. It is therefore intriguing that Guinee and Payne (1988) report that they found rhyme-like structures called multi-themed sub-phrases in songs.

These structures form similar beginnings and endings of adjacent phrases. The presence of these rhyme-like structures is strongly, positively correlated with the number of themes (i.e., the amount of material to be remembered) in a song, but not their duration, which suggests a possible mnemonic function, such as rhyme serves in human communication.

Foraging is another category of behaviors observed in the wild that suggests observational learning. Dolphins use a wide variety of foraging techniques unique to specific groups. For example, some dolphins in Shark Bay in Western Australia display a behavior called sponge feeding in which they carry a sponge over their rostrums while foraging. The hypothesis is that they use the sponge to avoid getting painful spikes from fish on the murky bottom. Although a genetic contribution is suggested by the fact that in one group studied 14 of 15 dolphins all belonged to the same genetic female line, the one exception indicates that if the trait is genetically controlled, it is not by a single gene. Supporting evidence is provided by another genetically unrelated, separate group, although they, too, share a common, female genetic lineage. However, there are members of these lines that are not sponge users, which weakens the case for a simple genetic transmission and strengthens it for social learning.

Another example of foraging involving dolphins is symbiotic fishing between humans and dolphins which has been reported since Pliny the Elder (~70 AD) described these interactions around the Mediterranean. More recent examples of cooperative fishing between humans and dolphins have been reported in multiple sites including Australia, Brazil, Myanmar, India, and Mauritania (Whitehead and Rendell 2015). The fishery off Laguna Brazil is well-described, although the origin of the cooperative arrangement is unknown. In response to fishermen wading in the mud flats, dolphins herd fish toward these shallows (a typical dolphin cooperative feeding behavior) where the fishermen are. Dolphins then engage in behaviors that alert the fishermen to throw in their nets. Not all dolphins participate, so it is important that the fishermen

recognize specific dolphins that engage in the cooperative enterprise. The dolphins do not herd the fish toward mammals other than humans. The benefit to humans is more fish, and we assume that this is also the case for the dolphins.

From a cognitive perspective, the flexibility and cooperation in which killer whales (*Orcinus orca*) engage as they forage are especially intriguing and indicate an ability to learn specialized skills. Killer whales are apex predators, and their prey vary extensively and include beaked whales, salmon, herring, seals, cephalopods, gentoo and chinstrap penguins, humpback whales, gray whales, gray seals, blue whales, sea turtles, minke whales, emperor penguins, elephant seals, sharks, deer and moose, and more! And while killer whales can hunt successfully alone, they usually hunt together. Sample capture methods include corralling, whales create a barrier in deeper water while an affiliate rushes the prey animal; and beaching, whales surf onto the beach and grab a pinniped while it is transitioning from swimming to getting onto the land. Young killer whales are often not as successful as adults in the same hunting waters, and sometimes adults accompany younger animals and float nearby while they hunt (Lopez and Lopez 1985). In these cases, the adults sometimes participate in the events without capturing prey. For example, in one area, an adult and juvenile would beach simultaneously about 4 m apart, and the adult would catch a sea lion and toss it toward the juvenile that either kept the sea lion it had already caught itself or, when it had no animal, would push the tossed sea lion or grab it with its mouth. Although the evidence for teaching is ambiguous, the younger whales' capacity to learn was very clear. Laboratory studies should investigate how similar skills can be transmitted among these animals.

One of the most interesting (if terrifying) examples of killer whales' collaborative hunting is the capture of seals on ice floes off the Antarctic Peninsula (e.g., Visser et al. 2008). Typically, small groups of whales (five to seven individuals) are involved, and they appear to choose prey that are on the frailest first-year sea ice. In one vivid and detailed description of a capture, a group of five

killer whale hunters began by spy-hopping around the floes to see possible prey. Upon spotting an adult crabeater seal, two whales submerged 15 m from the floe and swam together at and under it, which tipped the ice through “wave-washing” and broke it into pieces. Six wave-washes later, the piece of ice on which the panting seal was lying was quite small and had been pushed into deeper water via the whales’ rostrums and vortices at the floe’s edge created when the attackers submerged nearby. Bubbles blown near the ice’s edges cleared the surrounding debris. The encounter ended when one whale kept its rostrum on the ice while the other four lined up in pairs some distance from it, turned on their sides, and swam fast just under the surface as they blew bubbles and went under the ice on either side of the stationary whale. This action created a wave that tilted the ice in multiple directions and poured over it, washing the seal into the water where it ended up in a whale’s mouth. The sophistication of the skill set employed by these whales suggests cognitive capacities about which we should learn more.

Claims have been made – and disputed – for killer whale’s “culture,” and social learning is critical to that claim. (See Whitehead and Rendell 2015, for a review.) Transmission of skills suggests that killer whales may engage in imitation, and some data lend support. A few laboratory studies suggest behavioral and vocal imitation. For example, killer whales’ vocalizations are affected by their pool mates: Animals raised with bottlenose dolphins emit more click trains and whistles versus whales raised without dolphins that produce more stereotypic killer whale calls. Vocalizations in natural settings also suggest vocal flexibility. Like other odontocetes, killer whales emit a complex repertoire of whistles, echolocation clicks, and pulsed calls. In killer whales’ communication, pulsed calls are salient and the best studied of their vocal productions. These calls are generally stereotypic and sequentially patterned; the same call is often repeated. From the earliest scientific reports on killer whales’ vocalizations, the variability of call types between killer whale social groups was striking enough to garner the nomenclature

“acoustic clans” for groups that shared specific calls maintained at least in part through what could be termed cultural transmission.

## Learning and Memory

Dolphins remember well and display an ability to learn a variety of concepts. Dolphin’s working memory has been studied with delayed match-to-sample (DMTS) procedures. In most matching tasks, an animal experiences a sample item which is then removed, and the animal must find a replica of that item among a group of alternatives presented in a display. These DMTS tasks with dolphins have varied in many ways including offering two, three, or more alternatives; testing an associative conditional match in which the sample item is paired with a second different item (A to B) as well as the standard identity (A to A) match; and probe procedures in which small test trials are embedded within a larger session of familiar trial types (e.g., A’ to A embedded within A to A trials). For example, to determine that dolphins remember sounds, DMTS tests with open sets (e.g., multiple sample and test objects) of computer-generated sounds in an identity match showed that dolphins performed near 100% accuracy for delays of up to 1 min and over 80% at 2 min. When sets were closed, containing only two acoustic stimuli differing in frequency and amplitude modulation, performance started to drop off at 50 sec., probably due to memory interference among the few stimuli. Memory performance with conditional stimuli, in which different sounds previously mapped onto the sample stimuli were used as test stimuli, was similar to that of the identity match. Reducing the duration of the sample from the 2.5–4 sec used in previous tests to 3 msec did not substantively alter DMTS performance. Dolphins can also remember relative spatial positions after short delays. In addition, they exhibit the “recency effect” when presented with a list of sounds, i.e., they recall the later items better than earlier sounds in the list.

Dolphins also show memory for action events as indicated by asking a dolphin to do the same

behavior it has just done after a short delay. Dolphins demonstrate facility at this task and can repeat familiar behaviors and novel combinations of familiar behaviors. They also repeat behaviors that involve actions on an object when multiple objects are available. (See Mercado and Delong 2010, for a review.)

Studies of long-term memory are rarer, however, dolphins may remember signature whistles for long periods. Captive dolphins across sex and age (calf, juvenile, adult) classes showed memory for these whistles after periods of over 15 years in a habituation-dishabituation design (Bruck 2013). Although it is hard to know much about exposure levels to specific whistles over such long intervals, long-term recognition of signature whistles would probably be adaptive for long-lived animals in fission-fusion (groups that separate and come back together across time) societies, such as dolphins.

Many odontocete species, e.g., *Tursiops truncatus*, *Delphinus delphis*, *Phocoena phocoena*, *Inia geoffrensis*, and *Lagenorhynchus obliquidens*, are apt at instrumental conditioning tasks like discrimination learning across different modalities, especially vision and audition/echolocation. Often these learning studies focus on determining the boundaries of the species' perceptual systems, e.g., whether the dolphin can recognize a reference target when it is paired against a variety of other targets that differ from the reference target in fine-tuned ways (just barely thicker, just barely louder, etc.). (See Nachtigall 1980, for a review of echolocation discrimination learning.) Dolphins are good at negotiating such tasks.

At one time, development of learning sets (learning to learn), a rule-governed procedure, was considered a candidate for a comparative measure of intelligence. Although it may not have such general utility, it is still a notable cognitive ability, and the dolphin, Kea, provided sound evidence of its presence in cetaceans. She was presented with hundreds of pairs of sounds, one correct and one incorrect. The key evidence for understanding the concept was second trial performance: If the first trial was correct (e.g., sound A), then the same choice (A) was correct on the second trial; if the first trial was incorrect (e.g., sound B), then the

correct choice was the other alternative (A). Therefore, a win-stay/lose-shift strategy was required. Ultimately, her performance ranged from 75 to 90%+. Dolphins can also apply this concept (with specific sounds or their locations) to a reversal learning task in which the same stimuli reverse roles, i.e., the negative stimulus (B) becomes positive (the correct choice) and the positive stimulus (A) becomes negative. (See Herman 1980, 1986, and Herman et al. 1993, for reviews.)

Dolphins are good at learning abstract rules like the matching rule discussed earlier. They have also demonstrated generalized same/different discrimination which works as it sounds: The dolphin indicates whether two stimuli are the same or different by going to specific paddles (one for *same*, another for *different*) or staying at a paddle, for example, *same* versus moving to another paddle for *different*. Stimuli in these experiments have included auditory and 3-D and 2-D (planar) visual stimuli. Dolphins were able to classify pairs of unfamiliar three-dimensional objects in air on the first trial and then transferred this learning to presentation of unfamiliar planar objects underwater. They were also able to generalize the same/different concept to trials in which three objects were presented. They identified trials with three identical objects as same and trials with two same and one different object as different (Mercado et al. 2000).

Dolphins also appear to be able to learn an "innovate" rule: Do something you have not done within a set of behaviors or perhaps ever done before. The earliest example of this was a study of two rough-toothed dolphins (*Steno bredanensis*) that were required to produce a behavior not previously used in the innovation training sessions. One new behavior per session was reinforced. Familiar behaviors were common at first, but "new" behaviors began to appear regularly after some experience with the routine. Eventually, after 32 sessions and 16 reinforced (i.e., "innovated") behaviors, it became difficult for the experimenters to discriminate among behaviors (Pryor et al. 1969). Other similar studies with bottlenose dolphins have shown an ability to select familiar behaviors not recently used or novel behaviors. (For reviews, see Mercado and

DeLong 2010; Kuczaj and Yeater 2006.) “Newness” or “novelty” of behaviors is difficult to establish, so novel behaviors may in fact be rare behaviors not previously observed by the experimenters. Under any circumstances, unlike the previous win-stay/lose-shift strategies described earlier, this task required a win-shift/lose-stay strategy.

Most dolphin studies have dealt with the past or present, but a few studies have addressed planning. (For a review, see Kuczaj and Walker 2006.) Most of the evidence for planning in cetaceans comes from anecdotes such as the killer whale foraging incidents described above. Two experimental studies indicate that dolphins can engage in planning behavior. These dolphins were given a task in which four weights placed in an experimental feeding device within a specific timespan led to the release of a fish. The dolphins learned the task by observing a human putting the weights in the device only one at a time. When the weights were close to the device, the dolphins put them in as they had observed, one at a time. When the weights were later placed further away, the dolphins eventually carried multiple weights, taking the more efficient option; they avoided multiple trips and provided evidence of planning over time. In another study, the dolphins were presented with three feeding devices and a single weight. Each device contained a fish that would be released if the weight was placed in the device. Two of the devices had a hole in the bottom, which allowed the weight to fall through making it available to drop into another device. Since the lone device without a hole did not allow recovery of the weight, it limited the number of fish a dolphin could get to only one or two if it was used first or second. The strategic action was to select it last. That is exactly what the dolphins learned to do.

### Other Approaches to Cognition: Brain, Behavior, and Consciousness

This article’s title, *Cetacean Cognition*, evokes not only the perceptual, communication, and learning and memory studies described here but also their material basis, the brain, as well as the

general milieu of thinking that we often reference as “mind.” For humans, knowledge of mind can feel quite personal: One knows “mind” through one’s own mind, an experience typically known as phenomenal consciousness. As Descartes put it, “I think, therefore I am.” This section presents some information relevant to the brain and the search for aspects of consciousness in cetaceans.

Many species of cetaceans, most notably among the odontocetes, have large brains and high encephalization quotients (EQs), an index of brain size adjusted for body mass. For example, the brain size of a bottlenose dolphin (*Tursiops truncatus*) is about 1600 g, and its EQ is 4.14. (See Marino 2004, for a review of cetacean brain sizes.) For comparison, humans have a brain size of about 1300 g and an EQ of 7.0. The comparatively large brain size of cetaceans has led several researchers to postulate high levels of intelligence among cetaceans. Unfortunately, without detailed knowledge of neural connectivity, neuron density, and specific brain/behavior relationships, it is difficult to make definitive statements about the intelligence of cetaceans based on neurobiology alone. (See Oelshlager 2008, for more about the dolphin brain.) Behavioral measures provide the gold standard for understanding cetacean cognition.

Some studies have tried to access aspects of consciousness in dolphins through behavior, but the lack of a clear characterization of consciousness and the behaviors that require it precludes conclusions on this score. Approaches include mirror/video self-recognition and metacognition studies. (See Harley 2013, for a review.) Most of the self-recognition studies used the mirror-mark test in which an animal is marked with a visible (colored/opaque) or invisible (clear) fluid which creates, respectively, mark versus no-mark/sham-mark conditions. The fluid is placed on a part of the animal’s body that it cannot see without a tool, e.g., a mirror or video camera. Most animals engaged in studies like these have appendages (e.g., chimp hands or elephant trunks) that allow them to touch the marked area, and researchers record touches and code other behavioral responses to the marks/absence of marks as social or self-referential. The dolphin’s streamlined body

and non-differential or ambiguous responses to the marks/absence of marks have made this method unprofitable thus far for studying dolphin self-recognition. Other similar lines of evidence used to address consciousness (e.g., self-imitation, identification of body parts) also run into challenges of interpretation.

Metacognition, knowing what one knows, was studied by having a dolphin listen to tones and report, via paddle presses, whether they were “high” or “low”; some tones were close to the edges of these high- and low-frequency categories. After training with two paddles, the dolphin was also allowed to choose a third “uncertainty” paddle that led to a delay and an easy (clearly high or low) trial. The dolphin learned to use this paddle when the tones were perceptually difficult to categorize. It may have known that it did not know how to categorize the tones, or it may have chosen the third paddle after delaying its own response or for some of the middle tones. Knowing that we do not know suggests this area for future work.

## Conclusion

The study of cetacean cognition is relatively new. These animals’ perceptual worlds are fascinating; their use of sound is unparalleled. Cetaceans’ communication systems are complex, difficult to interpret, and understudied; we have much to learn in this arena. Many cetacean species engage in social learning across contexts via a variety of mechanisms, which may support development of culture. They are flexible learners with good memories. The order Cetacea offers rich opportunities for future discovery.

<sup>2</sup>Psychology Department, St. Mary’s University, San Antonio, TX, USA

## Introduction

When animals are grouped in time and space, social behavior can evolve. If individuals only encountered each other once, they would not have the potential to establish a knowledge base about the other individual. When associations persist over time, individuals repeatedly come into contact with each other and establish a knowledge base of interactions. Repeated interactions lead to the development of relationships (e.g., dominance, cooperative foraging, and mating coalitions). A description of the various relationships in a group can lead to a description of the social structure of the group (e.g., polygamous,

female-bonded). Thus, the social structure of the group is based on an abstraction of the nature, quality, and patterning of relationships, and relationships are built upon a series of interactions between individuals. These interactions are mediated by signal exchange, communication.

Communication is ubiquitous among animals requiring a sender to produce a signal that might alter a receiver's subsequent action(s) or response. The exchange of information from one individual to another via a signal that typically elicits a response is communication (Perrin et al. 2009). The function of communication is diverse and covers topics ranging from mate attraction, maternal care, mediation of social relationships, group coordination, and more. For all animals, including cetaceans, signals are exchanged through a variety of modes (i.e., chemical, visual, tactile, acoustic) that are produced in air and water via both anatomical and physiological mechanisms (e.g., coloration patterns, behavioral displays, vocalizations, etc.). These mechanisms can generate communicative signals via a single mode or via multiple modes in order to augment the message. Communication allows individuals to establish and maintain relationships, convey information about internal states or reproductive status, and coordinate activities.

Cetaceans are fully aquatic and include two taxonomic groups: (1) odontocetes, or toothed whales; and (2) mysticetes, or baleen whales. The odontocetes include sperm whales (*Physeter microcephalus*), beaked whales, river dolphins, oceanic dolphins, porpoises, and the monodontidae [Belugas (*Delphinapterus leucas*) and narwhals (*Monodon monoceros*)], while the mysticetes are comprised of skim feeders (right and bowhead whales, *Eubalaena* sp. and *Balaena mysticetus*), rorquals [e.g., humpback (*Megaptera novaengliae*) and fin whales *Balaenoptera physalus*], and the bottom feeder or gray whale (*Eschrichtius robustus*). Cetaceans adapted their signaling to an aquatic lifestyle, for example, relying more on acoustic signals and less on chemical signals as compared to terrestrial species. Odontocetes and some mysticetes live in complex social groups that require consistent, coordinated mediation of relationships;

communication is key to a successful social life. To understand communication in a given species, it is important to know the mode of the signal (i.e., visual, acoustic, tactile, gustatory, or olfactory), medium in which the signal is transmitted (air and/or water), mechanisms of signal production (anatomical and/or physiological), function(s) of the signal (e.g., aggression/submission, mate attraction, parental care, territorial defense), and whether signals are single or multimodal.

## Components of Communication

For any two individuals to share information, to communicate, there are several required components. The *signal* is the vehicle by which two individuals share information. At least two individuals are involved in any communicative event—the *sender* and *receiver*. The *sender* selects the signal to convey a *message* to an identified recipient. The message is the content that the sender wants to provide to the recipient but what the recipient understands from the signal is its *meaning*. That is, the message can be modified by the context or setting in which both actors (*sender*, *receiver*) are placed as well as the recipient's history (i.e., predictive scenarios based upon memories of previous experiences) to yield the *meaning* of the signal by the receiver. Because the sender and receiver are different individuals and have different histories, the message and meaning of a signal are never identical. Drastic differences (e.g., in social experience, age, etc.) between the sender and recipient can result in miscommunication.

Acoustic signals can be conveyed to recipients that are not in view, which can result in miscommunication more readily than close-range signal use (e.g., visual or tactile modes). Production of a very low-frequency sound (e.g., 20 or 40 Hz) can broadcast a message over kilometers (Richardson et al. 1995), although the sender would have little control over whether the message is received or how the signal might be distorted during travel through ocean topography. The sender also has little-to-no control over who might hear the message (i.e., eavesdrop) on these sounds: predators, prey, competitors, or mates. For example, the fish-

eating ecotype of killer whale (*Orcinus orca*) in the Pacific Northwest uses echolocation to hunt and communicate with conspecifics while foraging whereas the mammal-eating killer whale ecotype hunts silently (Barrett-Lennard et al. 1996), likely because prey of the latter would hear the hunter's vocal signals. In contrast, high-frequency (e.g., 2–15 kHz) sounds travel over shorter distances and are likely to be received by a specific audience. For cetaceans, baleen whales typically produce very low-frequency sounds also called infrasound while toothed whales produce both sonic and high-frequency sounds called ultrasound.

### Modes of Communication Signals

Signals are the means by which individuals share information and they can be used independently or synergistically depending on the content and function of the message. In general, signals are transmitted through chemical, visual, tactile, and acoustic modes. Dudzinski et al. (in Perrin et al. 2009) reviewed examples of communication signals from within all modes available to marine mammals. For cetaceans, the olfactory lobes are much atrophied as is the external nasal anatomy; that is, the relaxed position of the blowhole in all cetaceans is closed. Thus, while dolphins and whales may have a rudimentary sense of taste, they likely do not possess a sense of smell. That said, recent research suggests that dolphins might actually sample chemical signatures in the urine or feces of conspecifics as a form of individual recognition (Kremers et al. 2016). Visual signals include body postures and color patterns that offer information about social activity or travel patterns, etc. Visual acuity is excellent in those species for which it has been studied; however, visual signals are limited by underwater particulate matter and visibility. Similarly, most cetaceans are quite tactile and share information through body rubs, touches, and other tactile signals. These signals are functional at close range. Because sound travels faster in water and over a relatively large area as compared to in air, underwater acoustic signals likely evolved to be the principal mode of information transmission for cetaceans (Perrin et al. 2009).

Acoustic communication includes both vocal (e.g., humpback song, dolphin whistles) and non-vocal signals (e.g., breaches, tail slaps).

### Acoustic Communication

Acoustic studies of whales and dolphins began in the mid-1950s (Au 1993; Richardson et al. 1995). Over the last 50+ years, recording and analyzing cetacean sounds have become relatively inexpensive and straightforward, but determining the context and function of sounds is much more difficult, especially since the advent of passive acoustic data collection that does not contain any associated behavior or vocalizer identification of acoustic signals. In addition to meticulous documentation of the context for call production, playback research is required to determine the function of sounds. For example, Deecke (2006) summarized several studies using playback techniques to examine the sound function. Still, the application of playback studies is often confounded for cetaceans because a one-one correlation between an acoustic signal and a behavioral function is not often available.

Sounds can be used for intrasexual selection to compete against other members of the same sex or to establish dominance to gain access to mates. Sounds are also used for intersexual selection to advertise fitness and strength among males to nearby females. Acoustic signals may help to maintain group cohesion or coordinate movements, defenses, or the activities of a social group of aquatic mammals. Killer whales are an excellent example of a marine mammal that regulates group movements and cohesion via acoustic communication; killer whale family pods use dialects for one mode (acoustic) of identification (Filatova et al. 2012) – even humans can readily recognize the vocal dialects of different family pods. There are also acoustic differences in call types between the different killer whale ecotypes (Barrett-Lennard et al. 1996), and evidence for cultural transmission of their dialects (Filatova et al. 2013).

Generally, the information animals send tends to be context-sensitive, especially to behavioral

state. In turn, receivers make inferences based on what they hear and react accordingly by integrating previous experience with emotional states and (likely) genetically influenced perceptions. Variation in sound(s) (e.g., frequency, amplitude, etc.) can be caused by different factors, such as levels of excitement, stress, background noise, or motivation. So, to understand the function of a sound, a researcher must know the role amplitude plays, as well as the context in which calls might be produced. High amplitude signals may emphasize a message or low amplitude signals may aid in selective communication between mother and offspring.

Even when a vocal signal has been well studied, context may factor into potential meanings; for example, male humpback whales produce complex songs comprised of units that form patterns grouped into phrases and finally into themes (see Mann et al. 2000; Au and Hastings 2008). These songs have long been considered important to the humpback mating system. Still, their exact function has been difficult to pinpoint with respect to function. Multiple hypotheses have been proposed regarding the function of these songs: intersexual interactions, mate attraction, male spacing, and social ordering (Mann et al. 2000). The explanation with the strongest evidence currently is that songs are used for mate attraction, namely males will begin singing after joining groups with mother-calf pairs and stop singing if lone males join the social group. Once the lone male moves on, singing restarts. Males that sing while with mother-calf pairs typically have greater reproductive success, suggesting that the songs may have evolved for mate attraction but have a cost since other males can hear the songs and may join for prospecting purposes, not social ordering.

One noted exception of a vocal signal with an agreed-upon, though historically much debated, function is that of bottlenose dolphin (*Tursiops truncatus*) signature whistles. In 1965, Melba and David Caldwell identified and investigated individually distinct whistles that they termed “signature” from recordings of identified captive bottlenose dolphins. The whistle contours (as represented on frequency versus time plots called spectrograms) were individually distinctive

and stereotyped in certain acoustic features. Since the late 1960s, signature whistles have been suggested for several species, including but not limited to Pacific white-sided dolphins (*Lagenorhynchus obliquidens*), Atlantic spotted dolphins (*Stenella attenuata* and *S. frontalis*), and spinner dolphins (*S. longirostris*). Much debate ensued over the years related to determining the function of signature whistles; Rachel Smolker and colleagues confirmed that mothers and their offspring use signature whistles during separations and reunions for bottlenose dolphins in Monkey Mia. The signature whistle is a contact call to maintain group cohesion and identify the location of the sound-producing dolphin (Smolker et al. 1993; King et al. 2014). Sayigh et al. (1990) determined that a unique signature whistle develops early in a dolphin’s life, and it may be created in relation to the signature whistle of a dolphin’s mother. Through playback studies, bottlenose dolphins were confirmed likely to produce the signature whistles of peers as a method of labeling or contacting those individuals (King et al. 2014). Whistle copying (aka matching) is produced by close associates (at least in bottlenose dolphins), which suggests an affiliative function in the maintenance of social bonds in a fission-fusion society (King et al. 2014). Signature whistles in bottlenose dolphins help maintain individual animal identities within a group. Bruck (2013) demonstrated that individual dolphins are able to recognize signature whistles of dolphins they were once housed with, apparently up to two decades previously. Other vocalizations have been linked to various behaviors in dolphins, including foraging and feeding behavior, excitement or anxiety, courtship, aggressive behavior, and sexual play (Herzing 1996).

### **Mysticetes – Acoustic Communication**

The Mysticetes or baleen whales are the largest cetaceans with females typically larger than males (Mann et al. 2000). Baleen whales have no teeth; they have keratinized material called plates that hang from the roof of the mouth that are used for filtering prey from the water. Most baleen whales make long seasonal migrations between feeding and breeding grounds, annually. There are

14 mysticete species comprising four families: (1) Eschrichtiidae (single species of gray whale), (2) Balaenopteridae (eight species of rorquals), (3) Balaenidae (four species of right and bowhead whales), and (4) Neobalaenidae (one species of pygmy right whale).

Baleen whales produce low frequency sounds that travel long distances in water. Sounds can range in duration from 0.5 s to several minutes, if not longer. Blue (*Balaenoptera musculus*) and fin whales produce very low-frequency calls, as low as 20–40 Hz (Richardson et al. 1995; Au and Hastings 2008), whereas humpbacks produce songs that can last tens of minutes and range from a few hundred hertz to 1.5 or 2 kHz (Mann et al. 2000). Male humpbacks also produce social sounds on the winter breeding grounds. Broadly, baleen whale calls have been categorized into simple calls (low frequency <1 kHz, narrow band, frequency- and amplitude-modulated), complex calls (broadband, 500 Hz–5 kHz, frequency- and amplitude-modulated), and grunts and knocks (<2 ms, 3 kHz–30 kHz) (Perrin et al. 2009). Mysticete chirps and whistles tend to be >1 kHz, but change frequency rapidly and are less than 0.10 s in duration. These pure tones involve harmonics and seem to be produced by most baleen whales.

Several social functions have been proposed for mysticete sounds that include long-range contact, assembly calls, sexual advertisement, greeting, spacing, threat, and individual identification; however, only rarely has a specific sound been associated with a given behavioral event. It is probable that sounds produced by mysticetes serve to synchronize biological or behavioral activities in listeners that promote subsequent feeding or breeding. Known and examined baleen whale sounds seem to fall into three basic categories: low-frequency moans, short thumps or knocks, and chirps and whistles. Low-frequency sounds (20 Hz) of blue whales are recorded across ocean basins at distances of several 100 km. Blue whales are the largest creatures to inhabit the earth; they traverse large expanses in a relatively short time. It is no wonder then that the social structure of these animals reflects a scale that we are only beginning to comprehend. However,

tracking the distinctive vocal behavior of this species may provide important clues. “Old blue,” a single blue whale, was tracked for nearly 80 days using its distinctive, repeated, 20 Hz signal received by bottom-mounted SOSUS (Navy hydrophone) arrays off the coast of the eastern U.S. (Perrin et al. 2009).

Additional calls produced by several species include moans, sweeps, pulse-like sounds, upsweeps, downsweeps, grunts, groans, songs, and more. For example, Clark (1990) documented southern right whale (*E. australis*) sounds in relation to behavior and found that their sounds were not random, but were related to social context and activity. Resting whales were least soniferous, whereas mildly social groups produced the most varied suite of sounds, including high, hybrid, and pulsive calls, body and flipper slaps, and forceful blows. Clark’s work showed that “up calls” functioned as a request for contact between whales. Minke whale (*Balaenoptera acutorostrata*) “boing” sounds went unidentified for 50 years; the calls were first identified in the 1950s but only confirmed recently as part of the minke whale repertoire (Rankin and Barlow 2005).

### Odontocetes: Acoustic Communication

Toothed whales produce many types of sounds broadly classified into two types: clicks and pulses (amplitude-modulated) and pure tones (frequency-modulated). The former are clicks, click trains, and echolocation while the latter are exemplified as whistles, chirps, screams, etc. that are used in communication. Not all odontocetes have been shown to produce whistles; however, all species are believed to produce pulsed or click sounds.

Burst pulses occur when dolphins release clicks so rapidly (e.g., 200–1700 clicks per second) that it is not believed that they are able to gain any sonar information from the returning click echoes. Burst-pulse sounds are a series of broadband pulses with substantial ultrasonic energy that have been associated with agonistic behavior, have an aural component (to the human ear) that sounds singular (though these calls are often composed of 100 s or 1000 s of individual clicks), and have been identified as expressing

emotional content or communicating excitement, agitation, and other emotions (reviewed by Herzing 1996). Dolphins of many species release bursts pulses when they are excited or angry, and burst pulses are thought to convey information about a dolphin's emotional state.

Blomqvist et al. (2005) found a very specific burst signal produced by bottlenose dolphins that appears to be a "play" signal – indicating to other dolphins that "it's time for games, so I'm not really being aggressive." Burst pulses can be extremely loud, and dolphins may use them during aggressive encounters – possibly to hurt the "ears" of other dolphins. Burst pulse sounds are often seen in a social situation where males are herding female dolphins, where burst pulses are directed at the genital region of the fleeing females (Mann et al. 2000; Herzing 1996). They have also been observed when a mother emits a loud burst pulse directed at a misbehaving calf (McCowan and Reiss 1995). Different types of burst pulse sounds used during aggressive encounters have been called "squawks" and "barks" – these click trains are often produced so rapidly that to the human ear they sound like a continuous sound, however, they are a series of tightly spaced clicks. It is not always easy to tell the difference between a burst pulse and an echolocation click train; only in the last few years are scientists understanding more on how dolphins use burst pulses in social situations.

Echolocation (also known as sonar or biosonar) comprises broadband, amplitude-modulated, short-duration clicks, with a peak frequency represented in the ultrasonic range (Au 1993). Burst-pulse sounds more often have a lower source level and shorter interclick interval than echolocation click trains, although both have a highly directional beam-pattern (Au 1993). Sperm whales produce codas or sets of clicks up to 30 kHz and from 1 to 90 clicks per second that may be used in echolocation. Some researchers propose that each coda or set of clicks is an identifier for the individual sperm whales when feeding in very deep water allowing their sounds to be detected at 10–15 km away (Antunes et al. 2011). Madsen et al. (2013) used DTags to study sound generation in sperm whales, suggesting that this species' head to be

the largest sonic generator on the planet. Air is recycled within the head for continued production of clicks while diving deep during foraging activity. Pilot whales (*Globicephala melaena*) also produce a variety of calls – both tonal and pulsed.

Whistles have fundamental frequencies between ~4 kHz and 30 kHz that likely contain higher harmonics (whole number multiples of the fundamental frequency), are omnidirectional, and are categorized according to their plotted spectrographic shape of the fundamental frequency with time. Examples of categorization contour shapes include constant frequency, upsweep, downsweep, concave (hill), convex (valley), or sinusoidal waves. Harmonics likely play a role in group coordination and movement, at least among Hawaiian spinner dolphins (Au and Hastings 2008); hearing the number of harmonics in a whistle likely plays a role with respect to which direction group members will move when commencing night foraging activity.

While all delphinids produce pulsed and click vocalizations, not all species whistle (Madsen et al. 2012). Generally, whistling odontocetes are highly social. Whistles can be pure tones, frequency-modulated, increasing or decreasing in pitch, or fluctuating in tone. Whistles are produced singly or in series and can possess harmonics or not. There are at least four groups of nonwhistling odontocetes, including the porpoise family (Phocoenidae, including Dall's porpoise *Phocoena dalli* and harbor porpoise *Phocoena phocoena*), Commerson's dolphins (*Cephalorhynchus* sp.), pygmy sperm whales (*Kogia* sp.), and sperm whales. For example, dusky dolphins (*Lagenorhynchus obscurus*) are one of the few nonwhistling delphinids; Vaughn-Hirshorn and colleagues compared dusky dolphin audio data from Argentina and New Zealand and showed that these dolphins likely use single, short duration sounds with a constant interclick interval, as well as closely spaced clicks for communication (see Würsig and Würsig 2010). Interestingly, these species do not have the single, thin, midline vocal fold found in most other species of odontocetes. For species that do whistle, there is experimental evidence from dolphins that indicates whistles can be generated by the left

phonic lip while click sounds can be simultaneously generated by the right phonic lip (Cranford et al. 2011; Madsen et al. 2012).

### Stereotypy

Stereotypical calls produced by members of a social group that vary among populations have been termed dialects and have been described in at least two species of odontocetes. In British Columbia, matrilineal groups of killer whales have repertoires of call types that are unique to each pod. Cultural transmission (a cognitive process based on social learning that results in the modification of current behaviors; Henrich 2001) has been implicated in the development of killer whale dialects (Filatova et al. 2013). In sperm whales, codas are stereotyped sequences of 3–40 broadband clicks usually lasting less than 3 s in total. Luke Rendell and Hal Whitehead categorized these codas into six acoustic “clans” for populations in the South Pacific and the Caribbean (see Au and Hastings 2008; Antunes et al. 2011). These vocal clans have ranges that span thousands of kilometers, are sympatric, and contain many thousands of whales. Like killer whale dialects, the codas produced by these clans may result from cultural transmission.

### Mimicry

Scientists have learned that dolphins are amazing vocal mimics – able to reproduce manmade whistle structures with precise accuracy (Caldwell and Caldwell 1972; Reiss and McCowan 1993). Dolphins produce whistles during social situations, when separated from peers, when excited, when happy, and when panicked (reviewed in Herzing 1996). Different whistles are produced in different situations, and scientists have been attempting to catalog and categorize whistles from different study populations for years. This is an extremely complicated process, and much has been written about how various species develop and use whistle communication. The whistles and other vocal calls of killer whales have received considerable attention (e.g., Barrett-Lennard et al. 1996), and scientists have discovered that family groups (clans) appear to reliably produce distinct categories of whistles and other calls that are stable across

time, and that appear to be taught to new members of the group.

### Nonvocal Communication

All cetaceans engage in nonvocal acoustic communication. Breaches, tail slaps, pectoral fin slaps, jaw claps, etc. are examples of actions or behaviors that have a percussive quality or function. These actions do not appear to be produced indiscriminately or reflexively, but rather are under the intentional control of the animal exhibiting the behavior. Baleen whales have been observed to produce a group of behaviors termed surface-active that can be viewed from the surface and involve one or more whale bodies or an extremity being shoved above the water and slapping or crashing back down onto the surface. These percussive behaviors are audible under water for several kilometers around a whale. Most toothed whales produce a slapping noise at the water surface using powerful strokes of their fluke that are called lob-tails or tail (fluke) slaps and of their pectoral fins, as well as “head” or “chin” slaps. Fluke slaps are often considered a sign of frustration or irritation though these actions have been documented during play among dolphins (Mann et al. 2000; Greene et al. 2011). These behaviors yield a percussive sound that can travel several hundred meters. While underwater, dolphins also have been observed to fluke slap at fish, other dolphins or nothing; the result is a loud clap-like sound with numerous tiny bubbles that cavitate from the water off the fluke tips. Several toothed whale species produce a jaw pop or jaw clap during aggressive contexts that include males herding females during socio-sexual activity (Mann et al. 2000).

Dusky dolphins are perhaps the most acrobatic delphinid producing three types of leaps confirmed to be functionally related to foraging and socializing activity; the three types include head-first re-entry leaps, noisy leaps, and social, acrobatic leaps. Resulting sounds from their breach-like leaps have been described to travel up to 1 km (Würsig and Würsig 2010): the noisy leaps likely function to draw peers to a fish ball while also disorienting prey keeping them tightly schooled. Upon water re-entry after a spin, a

breach, a back slap, or a head or tail slap, Hawaiian spinner dolphins generate omnidirectional noise that propagates over short to intermediate distances. Some bottlenose dolphins (*Tursiops* sp.) use tail slaps to create a percussive bubble production in shallow waters over sea grass beds to scare fish from vegetative cover, termed *kerplunking* (Mann et al. 2000). Many odontocetes produce loud tail slaps at the water surface, which seem to indicate distress or aggression.

Both baleen and toothed cetaceans of all sizes breach (i.e., leap either partially or fully out of the water). Though potential functions for breaching remain unclear, it is likely that the resulting percussive sound when a cetacean's body re-enters the water carries information to conspecifics in the near vicinity. Breaches likely function as a display during aggressive or agonistic activity or during play.

## Visual Communication

Although humans generally tend to think of communication occurring with sound (thanks in part to our reliance on language), much communication also happens within the visual modality. Visual displays can be simple (e.g., sexually dimorphic features) or complex (e.g., behavioral sequences) and can be detected both above and below the water surface depending on visibility (Reynolds and Rommel 1999). Movements and postures often are highlighted in species with conspicuous color patterns (e.g., killer whales, humpbacks). In clear water, visual signals provide cetaceans a close-range alternative to acoustic signaling; however, a display could inadvertently alert predators or prey. Visual cues include everything from gestures to movements to coloration. Disruptive coloration (spots, stripes, bold colors) likely evolved for social signaling, or to deceive prey and predators. Pelagic species tend to live in large, mixed-species schools with the most complex color patterns among small cetaceans.

Overt actions and gestures such as open-jaw threat displays, aerial leaps, tail lobes, flared pectoral fins, and S-shaped postures form the majority of behavioral visual displays expressed by cetaceans.

Color pattern complexity may be important for species and individual recognition, as well as social signaling (Thomas and Kastelein 1990). For example, Atlantic spotted dolphins slowly develop spots as they age, with adult dolphins covered in mottled spot patterns – this quickly conveys information about a dolphin's age (Herzing 1996). Many color patterns – like counter-shading and the distinctive black and white markings of killer whales – are likely used for camouflage or to help when hunting prey species. However, some of the markings also help species to quickly tell the difference between animals belonging to the same or different species.

Sexual dimorphism is rare in cetaceans. In general, males tend to be larger and bulkier – males are larger because they need to fend off competition from other males. Male Amazon river dolphins accumulate scars all over their body that turns their skin bright pink, making it easier to pick out males from females (Martin and Da Silva 2006). Male narwhals usually have a single long tusk – unlike females who rarely develop a tusk. This may be a signal to other males about the size and power of the individual sporting the biggest tusk (Perrin et al. 2009). For the harbor porpoise and many baleen whales, the female is actually larger than the male, but for the sperm whale, males are as much as three times larger than the females. These differences between the sexes signal vital information that individuals can use to determine how to approach social situations.

## Postures

Overt actions and gestures such as open-jaw threat displays, aerial leaps, tail lobes, flared pectoral fins, and S-shaped postures form the majority of behavioral visual displays expressed by cetaceans. Changes in posture can be used to communicate to conspecifics, predators, and prey. Posture and behavioral signaling can be used to synchronize actions among individuals or groups as a signal for group coordination or for social interaction (e.g., synchrony between male coalitions of bottlenose dolphins when herding a female, Connor and Krützen 2015). During aggressive encounters, dolphins may flare out their pectoral fins in an attempt to appear larger, and open their

jaws – a threat signal. Male belugas, dolphins, and gray whales hold S-shaped postures during courtship encounters with females, presumably a visual signal to females indicating the male's interest (reviewed in Hill et al. 2015).

### Bubbles

Cetaceans (Odontocetes) often release bubbles from their blowhole when making whistle sounds, although the release of bubbles does not always coincide with the production of whistles. Bubbles appear to be an extra communicative signal and can take a variety of forms: bubble streams, bubble clouds, and bubble rings. A large bubble cloud is a conspicuous signal and often is produced as a threat. Dolphins, belugas, and other toothed whales often blow bubble streams and bubble clouds in a variety of social situations, and while these are primarily visual signals, the production of a large bubble cloud also produces a distinctive noise that can likely be heard over short distances.

### Object Carrying

Some dolphins in Australia have been observed using sponges as foraging tools – not a communicative signal at all, but in the Amazon, the Boto (or Amazon river dolphin) has been seen carrying sticks and rocks in its mouth apparently as a visual display meant to impress potential mates (Martin and Da Silva 2006). Males will collect objects and often swim out of the water holding the rocks or sticks in the air before slowly sinking back into the water. These object carrying displays may signal to the females the male's worth and attractiveness to the females, although this hypothesis has not been evaluated fully. Moreover, it is unclear as to how these behaviors are acquired. Perhaps they are learned from other dolphins, or they may be innate tendencies. Additional research is needed to better understand the mechanisms operating behind these behaviors.

### Tactile Communication

Visual displays are useful for close-range communication and, because of close proximity, visual displays may readily become tactile signals. Extensive touching and rubbing occurs in

cetaceans in both managed care and free-ranging settings during play, sexual, maternal, and social (affiliative and agonistic) contexts using the rostrum, mouth, flippers, fins, flukes, abdomen, and the entire body (e.g., Dudzinski et al. 2010; Dudzinski and Ribic 2017). Perhaps one of the most important modes of signaling in a dolphin's world is the use of touch. Dolphins have skin that is quite sensitive to even the lightest touch. Dolphins are known to rub their bodies against each other and also to engage in intricate rubbing behaviors using the pectoral fins (e.g., Dudzinski et al. 2010; Dudzinski and Ribic 2017). Dolphins will rub their fins into the fins of other dolphins, engaging in a behavior that looks a lot like holding hands. Sometimes dolphins will seek out rubs by positioning their bodies under the fin of another dolphin. Most all of this type of tactile behavior is thought to be a sign of affiliative contact that is performed intentionally as indicated by preferences for partners and positions. Much less is known about touch in other cetaceans. Contact between free-ranging belugas occurs during large social congregations in shallow areas for belugas, but it is unknown if the contact is intentional, as implicated in the dolphins, or a byproduct of proximity. Research with belugas in managed care suggests that contact occurs primarily between young belugas, mothers and their offspring, and between males (Hill et al. 2016). Observations of free-ranging mysticetes like humpbacks and grey whales suggest that contact primarily occurs between mothers and their offspring. These limited observations suggest that there may be species differences in the frequency of touch and the participants involved.

Not all contact behavior, however, is friendly. Tactile contacts often are observed during aggressive behavior but are characterized by more overt actions, such as biting, raking, ramming, wrestling, and butting. During aggressive encounters, dolphins can body slam each other, butt heads (melons), and ram each other with their rostrums. They also smack each other with their powerful flukes, and have even been observed leaping out of the water at each other and slamming into each other while airborne. With sensitive skin, these kinds of aggressive contacts surely must hurt, and these are clearly aggressive signals.

An inclination for tactile responsiveness has been noted in the studies of wild cetaceans as well as of those individuals in managed care. Among mysticetes, the gray whales of San Ignacio Lagoon, Mexico, are noted for approaching and rubbing under small boats, and for their tolerance of petting by tourists. In the wild, both Atlantic spotted and bottlenose dolphins rub body parts against conspecifics as well as into the sand or along rocky edges. Affiliative contact behavior (petting, stroking, nuzzling) has been documented in many cetacean species (e.g., humpback and North Atlantic right whales, *Eubalaena glacialis*) and is especially common among mothers and their calves (Hill et al. 2016). Contact swimming bouts, where one dolphin lays its pectoral fin on the flank of a conspecific, have been recorded in bottlenose dolphins in Shark Bay, Australia (Mann et al. 2000). Dudzinski et al. (2010) confirmed that pectoral fin contact is conserved across dolphin species and habitats, as well as contacts sharing similar function across body parts contacted. All observed odontocetes in managed care seek and are receptive to gentle body contact. Mild tactile stimulation (e.g., rubbing of gums, flippers, or dorsal fin) serves as an effective re-enforcer in training of most delphinids.

## Cetacean Communication Cognition

As described previously, communication signals may be as simple as body coloration or posture presented or as complex as a series of behaviors or sounds produced. Signals may be expressed with or without intention, which is obviously difficult to assess. Signalers can actively emit a signal, whether acoustic, visual, or tactile, with an objective that it will be received by the receiver and responded to with an appropriate response. Similarly, a signal may be emitted reflexively stimulated by a particular stimulus. Unfortunately, we cannot ask the animals about the intention of said emitted signal. Rather, researchers must rely on behavioral patterns and context to determine questions of intentionality or cognition. For example, bubble streams are often produced at the same time as whistles by immature cetaceans. However,

air released through the blowhole is not necessary to produce a whistle. Thus, these bubble streams may indicate a lack of control over blowhole air release during sound production and are unintentional. By comparison, older animals may be able to “choose” when to emit bubble streams as they will produce the bubble streams with or without corresponding vocalizations. Moreover, these older cetaceans can manipulate the amount of air released and the bubble shape produced with apparent intention (e.g., bubble rings, bubble bursts, Perrin et al. 2009). In contrast, the disruptive coloration pattern or mottling of certain species or dimorphic characteristics, such as the narwhal tusk or the killer whale dorsal fin, are honest visual signals that are outside of cognitive control. Similarly, tactile and acoustic signals likely have both reflexive and cognitively mediated components. Cetaceans may choose to direct certain types of contact or sounds toward specific individuals or during certain contexts, or they may simply respond to a specific stimulus with a stereotypical response. There is increasing evidence that cetaceans are modifying their acoustic signals to combat the increase in anthropogenic noise within their ocean habitat, which is indicative of cognitive control (e.g., right whales get louder, Parks et al. 2011). Finally, as expressed before, the least understood signal is chemical communication. Observations have suggested that individuals will swim through the excrement of a conspecific, sometimes with a mouth open and sometimes not. Additionally, experimental discrimination studies and anatomical/physiological research have begun to provide corroborating evidence for possible chemical signals. However, it is highly unlikely that these signals are cognitively controlled, as the chemicals are produced by the body in response to internal processes (i.e., estrus, illness, metabolic processes).

## Summary

Cetaceans have an entire suite of communication signals at their disposal. Clearly, life history and environment play a role in dictating the type and context in which signals are emitted. Mysticetes

tend to travel in small groups and are spaced over large distances. Their primary communication mode inherently is acoustic-based. However, many species do socialize with each other during breeding seasons and at various feeding grounds. These close-proximity interactions are likely facilitated by the other communication systems. Odontocetes tend to travel in larger groups and inhabit many different types of environments, making a diverse but comprehensive suite of communication signals necessary. Turbid, murky waters make eyesight virtually useless underwater as in the case of botoes, which make the reliance upon acoustic signals, tactile signals, and possibly chemical signals much more critical (Hanke and Erdsack 2015). Much remains to be discovered about the various communication systems of cetaceans despite over 50 years of research effort.

## Definition

Cetacean diet refers to the types and amount of food taken by whales, dolphins, and porpoises, all of which belong to the mammalian order Cetacea.

## Introduction

Cetaceans are typically top predators in marine (and in a few cases riverine) ecosystems, i.e., they are situated at the top of the marine food chain, and they may play an important role regulating the populations of their prey and contributing to the stability of the ecosystem. Cetaceans have few natural predators aside from sharks, although killer whales (*Orcinus orca*) take adults and juveniles of other cetacean species and the bottlenose dolphin (*Tursiops truncatus*) is known to attack and kill (but not eat) smaller cetacean species such as the harbor porpoise (*Phocoena phocoena*). Recent evidence indicates that gray seals also prey on harbor porpoises (e.g., Leopold et al. 2015).

Present-day cetaceans have evolved from an original common design to be able to exploit different kinds of prey. Their morphological adaptations to different diets form the primary basis for the division of the order Cetacea into two suborders: the Mysticeti (baleen or *mustached* whales), which feed on small organisms such as zooplankton and small fish, and the Odontoceti (toothed whales, odontocetes), which feed mainly on fish and cephalopods. The mysticete whales are characterized by the presence of baleen plates, made out of keratin, a protein that is also found in other mammals' hair and nails/claws. The baleen plates hang from the upper jaw of the whale and form a filtering mechanism by which it is able to trap shoals of the zooplankton and other small organisms (e.g., krill, copepods, amphipods, and even small fish) that constitute its food. The small size of these prey does not limit the size of the whale, and, in fact, the blue whale (*Balaenoptera musculus*), which belongs to this group of cetaceans, is the largest living animal. In addition to the baleen plates, Mysticeti have enlarged mouths, adapted for the filtering of huge amounts of food. Because of the nature of the filter-feeding process, baleen whales might not be expected to display cooperative hunting. However, some species (notably humpback whales) may cooperate in groups of up to 20 individuals, using *bubble netting* to concentrate prey. One whale in the group dives to locate prey and herds them to the surface,

releasing air bubbles while spiraling toward the surface. The bubbles form a tubular *net* that *traps* the prey which the whales then take (see, e.g., Wiley et al. 2011).

As their name implies, most odontocetes have teeth, although the number and size vary greatly among species. Their prey ranges from small fish and crustaceans to the giant squid (*Architeuthis* spp.), remains of which have been found in the stomachs of sperm whales (*Physeter macrocephalus*). Those cetaceans feeding on squid (teuthophagous) tend to have fewer teeth or less visible teeth, while those feeding on fish (piscivorous) tend to have long jaws and numerous small teeth. Some odontocetes have developed echolocation, using the echoes returned when their emitted sound hits the target, to aid in the locating of food, and some also display cooperative hunting of prey.

In this brief overview, we draw examples largely from the Northeast Atlantic, but the general principles apply globally.

## What Do Cetaceans Eat?

As already mentioned, cetaceans eat a wide range of prey, in terms of both the type and size of animal consumed. Baleen whales typically feed on small crustaceans, but the type depends on the species of whale and also on the area. For example, in the Antarctic, the main prey of rorquals (family Balaenopteridae) (and of many other species) is euphausiids (krill), of which only one species, *Euphausia superba*, makes up the bulk of the diet of all these predators. In other parts of the world, other euphausiid species are consumed by whales (e.g., *Meganyctiphanes norvegica* in the North Atlantic) together with other crustaceans, such as copepods. Small fish are also known to be eaten, notably by minke whales. Rorquals search for shoals of small prey, and, when they find them, the whales are able to expand their furrowed throats letting big volumes of water and prey into their mouths. Once maximum capacity is reached, the whale uses the muscles in the throat to force water out through the baleen plates – which are shorter and broader than

those of the other families of baleen whales. The prey are retained by the baleen, and the whale then swallows the millions of small organisms that constitute its diet. Because of the way they feed and where their prey are found, rorquals are moderate to shallow divers and swimmers and show a coastal but also deep-ocean distribution.

Because the copepods and the other organisms on which they feed are relatively immobile, whales of the family Balaenidae are slow swimmers and shallow divers and tend to have a coastal distribution. They have long baleen plates but no furrows in the throat, and they feed by swimming with their mouths open, getting water in but making it pass through the baleen on its way out trapping the prey. Feeding can take place at the surface and in the water column, and when feeding at the surface, this type of feeding is called *skimming* or *skim feeding*. This family includes the right whales (*Eubalaena* spp.), so called because they were the *right whale* to hunt due to the ease with which they could be captured and the fact that they would float after being killed.

Gray whales (*Eschrichtius robustus*) (Eschrichtiidae) have specialized in taking benthic crustaceans such as amphipods and isopods at the seafloor.

Odontocetes have teeth developed to feed on fish and squid. Unlike most terrestrial mammals, these teeth are usually all the same shape (homodont), typically conical or spade-like, although male narwhals (*Monodon monoceros*) normally develop a single tusk (very rarely two tusks) that grows from one of the two teeth the species has retained. There are many species of odontocetes, which range widely in size from less than 2 m in length in the smaller porpoises to over 18 m in the sperm whale. Species feeding mainly on squid tend as a general rule to have fewer or less visible teeth, while those feeding on fish tend to have long jaws and numerous small teeth. It has been hypothesized (MacLeod et al. 2006) that the mode by which an odontocete captures its prey conditions the size of prey it can take, with those species that possess long jaws and many teeth able to capture a wide variety of relatively large prey (for the size of the predator) using their jaws as pincers and employing suction feeding.

Representatives of this group would include many small cetaceans such as the common (*Delphinus delphis*), striped (*Stenella coeruleoalba*), and bottlenose (*Tursiops truncatus*) dolphins and porpoises (e.g., *Phocoena* spp.). Bigger toothed whales such as the killer whale would also belong to this group. The diet of all the smaller species mentioned above has been recorded as being mainly based on fish but with some cephalopods also being consumed (e.g., Santos et al. 2013). Crustacean remains have also been found in some stomachs but usually as a minor component of the diet.

In odontocete species with fewer teeth (e.g., the beaked whales, family Ziphiidae), the food consists mainly of cephalopods which are ingested using suction feeding. This method of feeding, however, restricts the size of the prey that can be consumed, and therefore a relatively narrow range of prey sizes is usually eaten (MacLeod et al. 2006). This group includes species that are able to perform dives that are among the deepest and longest known in cetaceans, presumably in search of their prey. Oceanic squid of several families (Histiotteuthidae, Cranchiidae, Ommastrephidae, Gonatidae, etc.) has been reported as the main prey of most of these species (Cuvier's beaked whales, *Ziphius cavirostris*; northern bottlenose whales, *Hyperoodon ampullatus*; sperm whales, e.g., Santos et al. 1999). However, some beaked whales of the genus *Mesoplodon* have been found with only remains of fish in the stomachs.

The sperm whale could be considered an exception to the general rule, as a largely teuthophagous species in which the number of teeth has not been reduced (although teeth are only present in the lower jaw). It has been suggested (Clarke 1980) that teeth are only used to grasp prey, since fresh prey has been found generally intact in stomachs and because food has been found in the stomachs of young sperm whales in which the teeth had not yet erupted and in the stomachs of whales with deformed jaws (Rice 1989). Sperm whales have been found to feed on a wide range of cephalopod and fish species with a wide range of body sizes (see reviews by, e.g., Rice 1989; Whitehead 2003).

The sperm whale is known to dive to more than 1,000 m, as revealed by animals found dead entangled in undersea cables and damage to cables that was attributed to sperm whales even when the carcass was not found.

Finally, earlier we mentioned the killer whale or orca. While some populations (ecotypes) do feed on marine mammals including cetaceans, seals, and sea otters, others specialize on fish. They may also eat penguins, squid, turtles, seabirds, and even moose.

## Feeding Strategies

We have already touched on feeding mechanisms and feeding preferences in the previous sections without saying much about the behavioral processes involved. As noted, many cetaceans have apparently specialized in feeding on fish (piscivorous), while others specialize on cephalopods (teuthophagous). Some cetaceans take both kinds of prey.

It has been often asserted or assumed that, once a basic preference for (or adaptation to) feeding on fish or squid is taken into account, most cetaceans are opportunistic feeders, selecting their prey, in terms of species and sizes eaten, according to availability – the alternative being specialization, whereby a predator selects a *preferred* prey species and will only consume other prey types when the preferred prey is not available. These ideas about feeding strategies can be traced back through various paradigms, including optimal foraging theory (e.g., Hughes 1980) and functional responses (Holling 1959), but, as Dunnet (1996) pointed out, opportunism, selection, and availability are “in fact shorthand for very complex biological interactions about which we know only a little in quantitative terms,” and the existence of these strategies in cetaceans is difficult to prove (Santos et al. 2013).

In predators that can be readily observed in captivity or indeed in the field, and in which the behavior of individuals can be followed, it is relatively straightforward to gain insights into prey selection behavior. However, with the current methods to study cetacean diet, regardless of

whether dead or live animals are sampled, we normally have only a snapshot or average of diet choices. However, an approximation which has been explored is to analyze the relationship between prey abundance and their importance in stomach content samples. The rationale behind such analyses is that there would be a positive relationship between prey abundance and their importance in a cetacean stomach if the prey is a preferred prey. Because other prey would only be eaten only if preferred prey are not available, there would be a less clear relationship between abundance and importance in the stomach contents (and their importance in the diet would decrease as the abundance of preferred prey increases). However, direct comparisons between abundance of prey species and consumption by cetaceans are not always possible because of the different scales on which data on predator diet and prey abundance are usually available, and the spatial variability in occurrence of prey patches, such that environmental variables may be better predictors of prey occurrence than sampling the prey directly (Torres et al. 2008).

The selection pressures affecting diet selection may go beyond considerations of energetics and nutrients. Feeding on some prey can have lethal consequences, as evidenced by findings of dead cetaceans, which had apparently died from asphyxiation due to fish lodged in their throats. Interestingly, a recent study shows that bottlenose dolphins have learned to decapitate catfish, apparently to avoid ingesting spines which can cause fatal injury (Ronje et al. 2017).

## Methods to Study Diet

There are several methods available to infer the diet of cetaceans, and we will mention some of their advantages and disadvantages. Knowledge of cetacean diet can provide a valuable insight into their biology and their role in the marine ecosystem in addition to helping answer questions about the potential effect of predation on prey populations and on threats to cetaceans, for example, arising from interactions with fisheries (Pierce and Boyle 1991).

Knowledge of cetacean diets has improved over the years with the establishment of systematic data collection (latterly from strandings and bycatches) that has allowed access to larger sample sizes, development of new prey identification methods, and new techniques to infer the diet of individuals over longer time scales and various numerical and statistical tools (e.g., quantitative fatty acid signature analysis, mixing models applied to stable isotope data). Several reviews of methodology have been published, including Pierce and Boyle (1991) and Tollit et al. (2010), so we will not attempt to cover all available methods here.

### Stomach Content Analysis

When cetacean were hunted, information on diet was gathered by the examination of the stomach contents of recently killed individuals or observations of the food remains regurgitated by the whales after being harpooned. In some cases, the material observed led to mistaken assumptions, as can be seen from the following quote referring to baleen whales caught off Bermuda:

“Their feeding on grass, growing at the bottom of the sea, appeared by cutting up the great bag of maw, in which was found two or three hogsheads of a greenish grassy matter.” (Anon 1665)

Investigations on diet through the systematic identification and quantification of the prey remains found in the stomachs provided the first evidence about the prey species (and the sizes and amounts) consumed and allowed scientists to make inferences on the ecology of the whale and dolphins based on their diet. The late Malcolm Clarke pioneered the use of cephalopod mandibles (beaks) in whale stomachs to make inferences about diet, and, in some cases, cephalopod species new to science were first identified from remains found in the stomachs of deep-diving cetaceans such as the sperm whale and beaked whales (Clarke 1980).

Stomach content (and fecal and regurgitation) analysis is relatively straightforward in that it does not require specialized equipment. However, it is time-consuming, since it involves the identification, counting, and measurement of the hard prey remains (e.g., fish bones and otoliths, cephalopod mandibles, and crustacean exoskeletal remains)

present to characterize and quantify diet and to back-calculate original prey size. Prey identification can be aided by the existence of reference material and the availability of reference guides (i.e., Clarke 1986; Härkönen 1986), but experience in identification is also important. The process may be simplified by using only otoliths to quantify fish in the diet, but this can result in incomplete and biased results. A major issue, especially in relation to (calcareous) fish otoliths, is the effect of acid digestion which can reduce size, remove key identification features, and ultimately entirely dissolve otoliths, to varying degrees depending on the species and size of fish. Some authors have *corrected* for effects of digestion, while others recommend using only undigested prey remains.

The advantages of, and possible biases in, dietary information derived from the analysis of stomach contents of stranded and/or bycaught animals have been discussed in detail in the literature (e.g., in the reviews by Pierce and Boyle (1991) and Tollit et al. (2010)). Biases can arise both from the source of samples, e.g., stranded animals may not be representative of the population because sick/injured animals or animals feeding near the coast are overrepresented. Concerns have also been raised when the origin of the samples is fishery interactions, because bycaught animals could have been feeding near the nets and species present in the nets could be overrepresented compared to the typical diet. Biases also arise from the samples themselves, for example, due to digestion or to secondary ingestion, whereby the remains found include prey remains from the stomachs of larger prey. Even with these potential biases, stomach content analysis remains the most widely used method to determine the diet of cetaceans, because it can provide fully quantitative information. Such data are needed for trophic models that can help determine the role of cetaceans in the ecosystem. Many other approaches either lack resolution (e.g., bulk stable isotope analysis), are not fully quantitative (e.g., DNA-based prey identification), or rely on availability of stomach content results to facilitate interpretation (e.g., fatty acid and stable isotope analyses).

## Fatty Acid Analysis

Cetacean blubber (the vascularized layer of fat beneath the skin) can represent up to 50% of body weight and is used for energy storage, as an insulator, to aid in thermoregulation, and buoyancy, and gives a dolphin or whale its hydrodynamic shape. Blubber is mainly constituted by triacylglycerols consisting of three fatty acids each attached to one of the three carbons of a glycerol molecule with an ester bond through the oxygen atom. Although animals can synthesize fatty acids, these compounds are mainly incorporated through the diet (especially in the case of polyunsaturated fatty acids which are biosynthesized only by phytoplankton and macroalgae). Fatty acids from the prey are not degraded, but they accumulate in the blubber during the lifetime of the animal; thus, blubber fatty acid composition can reflect the diet over a period of days or months (Iverson et al. 1995).

Fatty acids have been used to infer the diet of predators following this principle, with the possibility to quantitatively determine the proportion of each prey type consumed by a predator using quantitative fatty acid signature analysis (QFASA) (Iverson et al. 2004), a numerical modeling approach that uses fatty acid signatures of putative prey species to estimate the most likely contribution of each prey species to the diet, based on the observed predator tissue composition.

Although, in comparison with stomach content analysis, analysis of fatty acids requires specialized equipment (e.g., a gas chromatograph), it has the potential advantage over the former that information on diet can be obtained from animals with empty stomachs, samples can be taken from live animals (using biopsies), and the technique provides dietary information integrated over a longer time period.

However, several issues need to be taken into account when interpreting fatty acid values: first, cetacean blubber is stratified, with differences between the fatty acid profiles of the inner blubber (which has a more recent dietary origin) and outer blubber (that has a more structural role); secondly, lipids break down during the decomposition of a dead animal, and fresh carcasses may be needed to obtain reliable fatty acid profiles. Thirdly,

although most fatty acids are incorporated from the diet, others can be biosynthesized (mainly short-chain fatty acids), and it appears that amounts deposited may not be exactly proportional to amounts ingested. Therefore, *calibration coefficients* are needed that take into account predator lipid metabolism and deposition when estimating diet using the QFASA approach. For seals, these calibration coefficients were calculated using captive feeding experiments (Iverson et al. 2004), but to date there are still no calibration coefficients for cetaceans, although recent work on polar bears proposes that diet and calibration coefficients can be estimated simultaneously from the same data set (of predator plus prey fatty acid profiles) (Bromaghin et al. 2017). Finally, QFASA assumes that the fatty acid compositions of *all* potential prey are known and it is also clear that prey fatty acid profiles vary with age, season, sex, area, etc., of the prey – and of course also with the diet of the prey.

Although quantitative fatty acid analysis has been more successful when applied to invertebrate predators (e.g., squid, for which calibration coefficients are apparently unnecessary), useful semiquantitative results have been obtained in cetaceans, e.g., seasonal changes in fatty acid profiles of porpoises broadly matched expected changes based on stomach contents (Learmonth 2006).

## Stable Isotope Analysis

Similar to fatty acid analysis, stable isotope analysis (SIA) follows the assumption that the isotopic composition in the tissues of a predator reflects the isotopic composition of its prey. Isotopes are different forms of atoms characterized by the same number of protons (the same atomic number) but different number of neutrons (hence different masses). The most commonly used isotopes are those of carbon ( $^{12}\text{C}$  and  $^{13}\text{C}$ ) and nitrogen ( $^{14}\text{N}$  and  $^{15}\text{N}$ ), although isotopes of sulfur and oxygen and strontium, among others, have also been used. These isotopes are all stable (non-decaying, hence nonradioactive) as opposed to, say,  $^{14}\text{C}$ . Lighter isotopes are preferentially exhaled or excreted when food is metabolized producing an enrichment of the heavier isotopes in the tissues of the

predator relative to its prey. This *fractionation* process takes place at each trophic level which means that the higher in the food web a predator is situated, the higher the enrichment of the heavier isotopes in its tissues and, in principle at least, this enrichment takes place in a predictable way. For carbon it has been estimated there is an enrichment in the ratio of  $^{13}\text{C}$  to  $^{12}\text{C}$  of approximately one part per thousand for each trophic level while for N, the increase is around 3% (Kelly 2000).

Having information on two isotope ratios in the predator provides very low-resolution evidence on diet composition, but stable isotope analysis is widely used to obtain data on the trophic position of individuals and populations and also to determine where the animal has been living, with C isotopes, for example, acting as chemical tracers of different sources of primary productivity (e.g., inshore versus offshore) and also varying with latitude. For these reasons, SIA has also been used to infer, or confirm, migration and population substructure of cetaceans (e.g., Fernández et al. 2011).

As is the case for fatty acids, SIA can provide information for animals with empty stomachs, and different tissues (with different turnover rates) can be used to provide information on diet integrated over different time periods (soft tissues, teeth, and bones can also be sampled). Another advantage of stable isotopes is that information can be obtained from specimens in museum collections, allowing us to reconstruct the past environment and trophic positions of individuals.

Again there are issues that need to be taken into consideration when interpreting the results from SIA. One of the most important is that the isotope fractionation, between the diet and the predator's tissues, can differ in different tissues (Tieszen et al. 1983). Captive feeding experiments in cetaceans suggest that the fractionation seen in C and N isotopes can be a long way from the *typical* values of 1 and 3% (e.g., Caut et al. 2011). In addition, isotopic fractionation can vary depending on food quality and the nutritional stress of the individual (Schmidt et al. 2004). Finally, it is important to note that sample extraction methods and sample storage can affect the

results obtained. In particular, the isotopic signatures of lipids differ from those of other body components.

Despite these issues, the advent of compound-specific SIA, in which isotope ratios are calculated separately for different amino acids, can greatly enhance the information obtained. The increased amount of data generated potentially provides much higher resolution of dietary composition (e.g., Matthews and Ferguson 2014; McMahon et al. 2016). Another relatively recent development is the calculation of isotope ratios in individual growth rings of *recording structures* such as teeth, such that dietary information can be obtained for each year of an animal's life (e.g., Borrell et al. 2013).

## Other Methods

Several other methods have been used to obtain information on the diet of cetaceans. These include direct observations of animals feeding at the surface or using underwater cameras attached to the animals or to nets or other structures; the collection of feces and discarded prey remains from the water after detecting feeding behavior, for example, in the case of whales filter feeding baleen whales; and the identification of the soft tissues of prey in stomach contents. The latter approach has evolved from the use of electrophoresis to identify prey proteins, through raising antisera to detect proteins of specific prey, to identification of prey DNA. Molecular prey identification, for example, based on mitochondrial DNA, is increasingly the method of choice for a wide range of marine predators (e.g., Parsons et al. 2005) and has become relatively much less expensive than when first developed. Fully quantitative DNA-based diet analysis remains to be developed: the amount of DNA of a particular prey species amplified may bear little relation to the amount of the species in the stomach contents.

## Conclusion

There are many reasons why knowledge of the diet and the feeding ecology of a cetacean species

may be useful. Firstly, it provides insights into its biology and ecology, including habitat preferences, prey selection, competition and resource partitioning with other predators, energy transfer, population substructure, etc. In addition, understanding the effects of predators on the populations of their prey, and how predators cope with changes in prey abundance, is essential to predict responses of marine ecosystems to perturbation. Finally, diet analysis can provide important insights into threats including prey depletion and fishery bycatch. The diet is the main route by which various pollutants enter cetaceans, including toxic elements, persistent organic pollutants, and plastics. By understanding diet, we can gain a better understanding of these various threats and therefore contribute the conservation of these species.

## Cetacean Life History

Malin K. Lilley, Kendal A. Smith and  
Natalia Botero-Acosta  
The University of Southern Mississippi,  
Hattiesburg, MS, USA

## Definition

Cetacean life history describes the reproduction, growth, and survival patterns for species in the mammalian order Cetacea, which includes whales, dolphins, and porpoises.

## Introduction

Cetaceans are a diverse order of water-dwelling mammals that inhabit all of the world's oceans and many freshwater ecosystems. Cetaceans are split into toothed whales (Odontoceti), which include dolphins and porpoises, and the typically larger baleen whales (Mysticeti). Cetacean species range from just a few feet long to 100 ft in length, can be very long lived, and have diverse patterns of behavior. Though the reproductive strategies of each species vary, most cetacean mothers invest considerable time gestating and caring for a single offspring at a time. Research on life history parameters has been collected via historic whaling records, stranded and bycaught animals, and current research which includes using photo-identification to track individuals across years, tissue sampling, radio-satellite tagging, use of aerial surveys, and information obtained from cetaceans in human care. The general parameters of both mysticetes and odontocetes are discussed in each section; however, research for many species remains ongoing, as most statistics are based on a limited number of species within each suborder. Learning about each species' life history is necessary for a better understanding of how each survives in a variable, aquatic environment and how conservation efforts can be better focused to increase rates of survival amidst many anthropogenic threats.

## Reproduction

### Mating

Traditionally, researchers agree that cetaceans do not conform to a monogamous mating system but instead have suggested several alternatives including one male mating with several females, one female mating with several males, and both sexes having multiple mates (Brownell and Ralls 1986; Clapham 2000; Connor et al. 2000). In some species, females may be selective in choosing male partners, while in other species males form alliances with other males in order to guard and mate with a female who is ovulating.

In a mating system where females have multiple sexual partners, males have evolved mating strategies that utilize sperm competition. Sperm competition can be inferred from the presence of large testes size combined with absence of secondary sexual characteristics, the occurrence of solitary individuals and small group sizes, as well as from the infrequently recorded agonistic behavior between males. Such features are present in right whales (*Eubalaena australis*), bowhead whales (*Balaena mysticetus*), gray whales (*Eschrichtius robustus*), pilot whales (*Globicephala* spp.), and harbor porpoises (*Phocoena phocoena*) (Brownell and Ralls 1986; Frasier et al. 2007; Learmonth et al. 2014). In other species such as humpback whales (*Megaptera novaeangliae*) and sperm whales (*Physeter macrocephalus*), increased agonism within male-male interactions, smaller testicular and penis size, and some degree of biased reproductive success appear to be the alternative to sperm competition (Brownell and Ralls 1986).

### Age at First Birth

Females consistently mature faster than males because their sexual maturity depends exclusively on physical maturity (Perrin and Reilly 1984). Males tend to take longer to mate, as physical maturity often precedes the social competence necessary for mating (Clapham 2000). Sexually mature females are identified by the presence of the corpus luteum and corpus albicans, temporary

endocrine structures in the ovaries. Given paternity uncertainty, observations with a dependent calf are another indicator of sexual maturity in females, but not for males. Rather, the presence of spermatozoa in testes and epididymis and the change in diameter of seminiferous tubules would be the main indicators for males. The age at which sexual maturity is attained greatly varies in cetaceans. Sexual maturity in toothed whales ranges between 3 and 20 years old, with most species converging on a modal age of 10–12 years (Perrin and Reilly 1984). For baleen whales, females tend to become sexually mature between 5 and 8 years of age, while most males will not sire a calf until they are at least 15 years old (Pomeroy 2011).

### Birthing Interval

The number of years between when calves are born varies widely for both mysticetes and odontocetes. For baleen whales, estimates range from 1 to 5 years, with a modal interval of 2–3 years (Clapham 2000; Lockyer 1984). Toothed whales show an even greater variation with birthing intervals of 1–14 years (Perrin and Reilly 1984). However, most species have a modal interval of 3 years (Gaskin et al. 1984). Some species, including humpback whales, harbor porpoises, vaquita porpoises (*Phocoena sinus*), and bottlenose (*Tursiops* spp.) and common dolphins (*Delphinus* spp.), may have consecutive pregnancies and may nurse while also becoming pregnant again (Perrin and Reilly 1984). The interbirth interval is often dependent on the duration of the pregnancy and the duration of calf dependency, which can range extensively between species.

### Parental Care

All cetaceans give birth to a single, very precocious calf. While multiple fetuses have been documented in several species, its occurrence is extremely unusual (Lockyer 1984). Because of paternity uncertainty, parental care is exclusively provided by females. While toothed whales rely on a relatively lower energy investment during pregnancy compensated by a long period of calf dependency, baleen whales require a much higher energy investment during pregnancy,

compensated by a significantly shorter calf dependency period (Oftedal 1997). Most cetacean gestation periods last between 10 and 12 months (Pomeroy 2011). Species with extreme gestation periods include pilot whales (15–16 months), sperm whales (16–17 months), beluga whales (*Delphinapterus leucas*, 15–16 months), and killer whales (*Orcinus orca*, 12–17 months) (Perrin and Reilly 1984).

Lactation is likely the most energetically expensive aspect of cetacean reproduction. Females produce milk high in fat and protein content, which allows for rapid growth and development of calves (Lockyer 1984). Baleen whales typically nurse their calves for 4–10 months (Clapham 2000). Weaning in most migratory baleen whales falls on a continuum; some calves separate from their mothers during or after the summer feeding season, while others return to breeding grounds before separation occurs. Toothed whales show greater variability regarding the duration of lactation periods with estimates ranging from 8 up to 60 months. Most species appear to converge on estimations of 18–20 months (Gaskin et al. 1984; Perrin and Reilly 1984).

### Senescence

In certain cetacean species, including killer and pilot whales, females can live over 20 years after the birth of their last calf (Marsh and Kasuya 1986). This post-reproductive period of the life span is called senescence. Two main hypotheses have been proposed to explain the occurrence and maintenance of this phenomenon. Kinship theory states that post-reproductive females maximize their inclusive fitness by assisting their offspring, ultimately improving offspring survival and reproductive success (Foster et al. 2012). Alternatively, Nichols et al. (2016) proposed that senescence was originally the result of asynchrony between reproductive system aging and aging of the rest of body and that female senescence may be adaptive in species where adult males remain in the same group or home habitat, therefore reducing the chance that a female will mate with her adult male offspring.

## Growth

### Neonate Size

When compared to other mammalian species, cetacean calves are large in proportion to adult size. At birth, odontocete calf length can range from 40% to 48% of the mother's total body length. Two of the smallest cetacean species, harbor porpoises and vaquita porpoises, have a high calf length to mother length proportion with calves born 70–75 cm and 60–76.4 cm long, respectively. Birthing larger calves likely increases chances of calf survival for these smaller cetacean species. Atlantic bottlenose dolphins are born approximately 116 cm for male calves and 114 cm for female calves. Beluga whales are born on average 130 cm, whereas false killer whales (*Pseudorca crassidens*) are born 160 cm. Calves of larger odontocete species, such as pilot whales and killer whales, are even born as long as 180 cm and 257 cm, respectively (Perrin and Reilly 1984). From birth, mysticete species tend to be larger overall than odontocete species with comparatively smaller proportion of calf length to mother length (29%). The fin whale (*Balaenoptera physalus*), a large baleen species, is born on average 6.5 m in length and can weigh 1.75 tons, while the humpback whale calf is approximately 4.5 m, and the blue whale (*Balaenoptera musculus*) calf is born 6.5 m (Whitehead and Mann 2000).

### Patterns of Growth

Although cetacean species span a large range of body size, most species follow a similar trend in physical growth. Rapid neonatal growth occurs immediately after birth and throughout weaning. Vaquita porpoises, a smaller odontocete species, can reach 62% of adult length by the second year of life (Hohn et al. 1996). For both odontocete and mysticete species, rates of growth tend to slow once weaned. In general, mysticetes tend to wean earlier than odontocete species likely as a result of differing foraging strategies. Mysticetes have evolved disproportionately large mouths with thin keratinous plates rather than teeth which allow them to strain schools of small fish

and invertebrates from the water, ensuring foraging efficiency (Wursig 1989). In contrast, odontocetes use more specialized foraging styles that typically require rapid and precise movements. Foraging for odontocetes may be more difficult for calves, so calf survival may largely be dependent on a longer nursing and weaning period that provides opportunities for learning and becoming efficient at these more specialized foraging techniques.

Harbor porpoises exhibit rapid growth until approximately 6 years old, likely to maximize size and effectively increase calf and juvenile survival. Atlantic bottlenose dolphins and Amazon river dolphins (*Inia geoffrensis*) exhibit similar patterns of development, growing approximately 4.8 kg per year for the first 4 years. Likewise, killer whales grow rapidly for the first 3 years of life. Bowhead whales, a large mysticete species, typically grow in length and weight rapidly until they complete weaning at around 1 year old; body growth rates then begin to decrease, while the head and baleen continue a steady growth rate until around 5 years old (George et al. 1999). Growth rates usually slow until sexual maturity, when some species such as killer whales and Atlantic bottlenose dolphins exhibit a short increase in male growth rate in preparation for mating. Killer whales at sexual maturity also exhibit a spike in dorsal fin growth, where male dorsal fins reach heights of 1.8 m, while female dorsal fins only reach heights of 0.9 m (Kastelein 1998).

Most cetaceans overall show some degree of sexual dimorphism, where one gender grows larger or faster than the other. Females tend to reach lengths 5% longer than males in baleen whales, porpoises, and river dolphins. In harbor porpoises, for instance, females (95 mm/year) even grow faster than males (55 m/year). Larger females can advantageously birth larger calves with higher chances of survival. However, in other odontocetes, such as beluga whales and Risso's dolphins, males attain lengths 2–10% larger than females. Sperm whale males, the largest odontocete species, can even reach lengths 60% larger than females. In certain

species such as the pilot whale where males mature 6–7 years after females, the larger sex likely physically matures years after the smaller sex, simply because growing larger may take a longer time. For large species with longer life spans, such as bowhead whales, growth rate likely remains steady until mid-life, approximately 40–50 years old, when growth rates decrease and stabilize (George et al. 1999).

### Maximum Size

While more data remains to be collected for some larger cetacean species with longer life spans, the literature contains extensive data on smaller cetacean species, particularly odontocetes, which have a comparatively shorter life span. Harbor porpoises only reach 155 cm for males and 165 cm for females (Lockyer 1984). Finless porpoises (*Neophocaena phocaenoides*) can reach up to 192 cm for males and 175 cm for females (Gaskin et al. 1984). Another small odontocete, Risso's dolphins (*Grampus griseus*), exhibits a large range of adult lengths, 193–308 cm for females and 186–323 cm for males. The Atlantic bottlenose dolphin and the Amazon river dolphin can reach similar maximum lengths of 250–270 cm for the Atlantic bottlenose dolphin and 196–255 cm for the Amazon river dolphin (Reidenberg and Laitman 2009). Larger odontocete species such as killer whales can display striking sexual dimorphism at maturity, where individuals grow up to 770 cm for females and 900 cm for males (Reidenberg and Laitman 2009). Likewise, pilot whale adult males can grow as long as 570 cm and weigh up to 2,000 kg, while adult females only grow as long as 380–450 cm and weigh on average 600–1,000 kg (Reidenberg and Laitman 2009). Unencumbered by physical boundaries characteristic of terrestrial environments or gravity, some mysticete species can reach extraordinary lengths. For instance, fin whales during their 80-year life span can reach lengths of 22.5 m for females and 21.5 m for males and can attain weights as large as 80 tons (Reidenberg and Laitman 2009).

## Survival

### Longevity

Assessing aspects of cetacean survival can be a challenging endeavor, given the difficulty in following these animals over extended periods of time and considerably large habitats. The use of satellite tagging (Fig. 1) and photo-identification can help; however, research in this area will only continue to grow over time.

The average and maximum life spans of many cetacean species are still not established, though the existing research indicates that these figures vary greatly between species and even vary between different populations of the same species. In general, larger species have a longer life span, and smaller species have a shorter life span (Whitehead and Mann 2000). The bowhead whale has been found to exceed 100 years old, whereas other mysticete species can live 45–95 years (George et al. 1999; Whitehead and Mann 2000). On the other end of the spectrum, some small odontocete species may have a

maximum life span of just over 20 years (Whitehead and Mann 2000). Many harbor porpoises may not exceed 20 years of age (Whitehead and Mann 2000). Larger odontocete species such as the pilot whale and the sperm whale may live as long as 60 years and 85 years, respectively (Whitehead and Mann 2000). Killer whales are reported to have a typical maximum life span of 80 years for females and 60–70 years for males, though some individuals are known to live to older ages; however, these ages may vary in different populations of killer whales (Olesiuk et al. 2005). Bottlenose dolphins are reported to have an average maximum age of about 45–50 years, which may also vary according to population (Whitehead and Mann 2000). Bottlenose dolphins in both the wild and human care have even been reported to reach 60 years of age.

The above numbers indicate the maximum age these species may reach, but these may differ from the average life expectancy. For example, some populations of killer whales comprised of individuals 80 or 90 years old may only have an average

**Cetacean Life History, Fig. 1** Satellite tag deployed on a humpback whale (Photo by Fernando Félix Grijalva)

life expectancy of 30–45 years (Olesiuk et al. 2005). Similarly, bottlenose dolphins may have an average life expectancy of 15–25 years, depending on the population (Stolen and Barlow 2003). These estimates attempt to include individuals that die from injury or illness prior to maturity and calves that do not survive, though it can be difficult to estimate this figure. In Shark Bay, Australia, 56% of known calves survived to age 3; however, calf mortality may vary for other populations (Mann et al. 2000).

### Predation

Cetaceans do not face many other ocean-dwelling predators. Sharks are known to attack both young and adult odontocetes, with most reports being in well-studied populations of bottlenose dolphins. In particular the dolphins in Shark Bay, Australia, face a higher rate of predation than other populations, with almost 75% of the study population having shark bite scars (Heithaus 2001).

The other predators of cetaceans are the transient ecotype of the killer whale, which sometimes prey on small odontocetes, such as Dall's porpoises (*Phocoenoides dalli*), and the calves of larger mysticete species, such as the humpback whale (Baird 2000).

### Movement Patterns

Predation by killer whales and seasonality of prey availability are both hypothesized reasons that some species, including the humpback whale, migrate thousands of kilometers each year (Corkeron and Connor 1999). Lower latitudes and shallow, warm water environments during the winter months provide increased protection for pregnant humpback whales and calves from both killer whale predation and male conspecifics attempting to mate. Females and their calves return to colder waters during the summer season to take advantage of the abundance of prey in the nutrient-rich waters. Migratory timing for humpback whales is closely linked to reproductive success (Craig et al. 2003). The distribution of humpback whales within wintering grounds appears to vary by temperature, which suggests that warmer waters may influence reproductive success (Rasmussen et al. 2007). Other large

species, including the sperm whale, gray whale, and blue whale, migrate as well, though not all members of a species migrate every year (Wursig 1989).

Many odontocete species also display movement patterns that may include inshore/offshore seasonal movements, following prey along the coast, or diurnal movements to hunt and avoid predators (Wursig 1989). Movement patterns may also differ by sex. For instance, male belugas show more dispersal than females, although most animals seem to return to a phylogenetically distinct summering ground (O'Corry-Crowe et al. 1997). Amazon river dolphins also move seasonally with their prey, and males and females typically occupy different parts of the habitat, likely to protect mothers and calves (Martin and da Silva 2004). Finally, the different ecotypes of the killer whale have distinct movement patterns. Some killer whales remain in one area year round, while others travel more extensive distances, though it is unclear if any north-south migration occurs (Baird 2000).

### Feeding Ecology

Closely linked to migration in many species is the location of the optimal food source. The food sources of cetaceans can vary greatly, from the marine mammals consumed by some killer whales to the small krill consumed by many mysticetes. The flexibility in cetacean foraging strategies can be seen not only in their diverse food sources but also different hunting or prey-capture techniques. Killer whales are known to work as a cohesive unit to wash prey from floating patches of ice, chase pinnipeds up onto beaches, and stun fish with their flukes before capturing them (Baird 2000). Bottlenose dolphins are also known to chase fish onto beaches, use sponges over their mouths when foraging, and create clouds of muddy water to trap fish (Whitehead and Rendell 2014). Other odontocetes consume a variety of fish, squid, and other available prey.

Mysticetes are well known for their migrations to nutrient-rich feeding grounds in both Arctic and Antarctic waters. While some whales, such as the bowhead whale, do not leave Arctic waters, many other species travel to these colder waters on a

seasonal basis to take advantage of the abundance of prey (Corkeron and Connor 1999). Other variations in movement and feeding patterns also exist. Humpback whales migrating from Antarctic to tropical waters continue feeding on fish and krill throughout the migration, a behavior which may vary by prey availability along the migration route.

## Conclusion

As was discussed in each section above, extensive diversity exists among cetaceans in reproduction, growth, and survival life history parameters. There are several methods of research which have only just begun to expand comprehensive, detailed knowledge for more cetacean species. One of these methods is the use of drones which are able to obtain aerial videos and even samples of a whale's exhalation with minimal disturbance to the animal (Fig. 2). Another method includes analyzing fecal matter from whale defecation and skin samples from breaching whales collected opportunistically by nearby research vessels. Investigating paternity is also a relatively

promising field, as genetic analysis methods become more accessible for field researchers studying wild populations (Fig. 3). Paternity assessment has revealed the polygynous mating system in humpback whales, where some males sire up to three offspring, while others sire none (Cerchio et al. 2005), as well as the effectiveness of male bottlenose dolphins' alliances in successful mating.

Finally, the increase in sufficiency of satellite tagging can help answer many questions regarding cetacean life history, including migratory patterns, behavior, and habitat use. More attention should be directed toward developing tagging methods that are appropriate for younger animals, as there is a lack of information on early life history for many species. Improvements in tag design, technology, and the methods of attaching tags continue to be an area of focus for research in many species. Based on life history parameters, models for specific populations of animals can be created and used to assess that population's recovery from the impacts of whaling, the effects of current anthropogenic threats, and predictions of future population dynamics that can be used to inform conservation policies. The future of many

## Synonyms

## Movement

## Definition

The morphology, physiology, and behavioral aspects of cetacean movement through water.

## Introduction

Cetaceans have evolved to thrive in their own unique environment. They carry out all aspects of their lives in water, unlike other marine mammals, such as seals and sea lions (pinnipeds),

otters (mustelids), and polar bears (*Ursus maritimus*), who exit their aquatic environment periodically to mate, raise young, rest, or thermoregulate. Transportation via water is economical for cetaceans because less energy is spent supporting the weight of their body (Fish 1993). Cetaceans are neutrally buoyant in water because their body tissues have similar densities to the water they live in. Movement underwater is also advantageous because it is easier to generate propulsion (Fish 1993). The challenge of living full-time in water, however, is these animals are subject to a greater amount of drag forces that act upon them as they move through their environment because water is denser and more viscous than air. It is for this reason cetaceans adapted to have specialized morphology, physiology, and behavior to facilitate exceptional underwater locomotion.

## Morphology

Many aspects of cetacean morphology ultimately aid them in reducing drag, the resistance to movement in water, while also providing better means of maneuverability, and lift and thrust production (Reidenberg 2007). Most noticeably, their characteristic body shape combats drag by having a rounded front edge of their beak-like rostrum, a wider middle body, and tapering end from the mid-body to their tail flukes, resembling a tear-drop or torpedo shape. This fusiform shape streamlines and allows water to flow more efficiently around the body, creating less wake (Fish et al. 2008). The flukes are also fusiform shaped, much like wings of an airplane or a boat propeller. The leading edge is thick and rounded around the tail stock and gradually decreases in thickness to the trailing edge to streamline and help produce greater thrust for locomotion (Fish et al. 2007). The cross-section of flukes are very similar in all species, but there is some variation between species in the planar geometry which dictates their locomotion efficacy (Fish et al. 2007). Some differences in planar shape include the area, distance between the two tips, and the interaction of these two measurements to form the aspect ratio (Fish 1998) (see [Physiology](#) section).

Cetacean appendicular skeleton aids in a streamlined body design, with the loss of exterior hind limbs, and forelimbs that are scaled down and sculpted for optimal hydrodynamic performance (Williams 2009). Today, cetaceans only have traces of hind limb skeleton that can be found in the body wall. Its presence is variable in some species, occurring less often in odontocetes (the suborder containing toothed whales; Adam 2009). The forelimbs, pectoral fins (often referred to as flippers), are mainly used to stabilize the body and maneuver through their environment by generating lift and controlling flow of water around the surface of the fin (Weber et al. 2014). Unlike flukes and the dorsal fin, pectoral fins contain forelimb and digit bones. For this reason, they have greater variation in the shape and characteristics of their hydrodynamic properties depending on the skeletal structure of each species. Differences in shape can be linked to the movements necessary for species ecology and their individual foraging techniques. For example, killer whales (*Orcinus orca*) have round paddle-like pectoral fins designed for excellent maneuverability to help them pursue agile prey, whereas fin whales (*Balaenoptera physalus*) have pectoral fins that are more pointed and tapering, which provide low drag to support their lunge feeding techniques (Weber et al. 2014).

Another characteristic external feature that increases cetacean locomotor efficiency is the absence of fur. The properties of fur which allow it to hold heat well are greatly reduced when submerged in water. Fur also has the disadvantage of creating unwanted drag (Reidenberg 2007). Cetaceans possess a thick integument with a waterproof sheet of skin and underlying layer made of fat, and elastic and collagenous fibers called blubber. The outermost layer of skin (epidermis) is elastic and smooth which cuts down drag because there is less friction being created when water slides past the body. Another important aspect of cetacean skin is the rate at which epidermal cells are produced. Compared to humans, bottlenose dolphin (*Tursiops truncatus*) epidermal cells are produced 250–290 times faster (Fish and Hui 1991). The high turnover rate of skin cells helps minimize drag by decreasing the likelihood that smaller organisms like barnacles or natural slime will attach to the

body and create unwanted resistance (Fish and Hui 1991). There are some hypotheses of hydrodynamic capabilities regarding the unique internal structure of cetacean skin, such as a dampening function from its elastic properties, and flow control by dermal ridges. However, neither of these hydrodynamic functions have been fully demonstrated (Fish 2006; Cozzi et al. 2017). Underneath the skin, a thick layer of blubber helps to insulate, store energy, control buoyancy, and reduce the effects of drag. As mentioned previously, cetaceans have a fusiform shape. Blubber helps to mold the body into its shape by being unevenly layered in a way that tapers the body more gradually over the muscles, especially between the mid-body and flukes (Iverson 2009). Along with its ability to help form a streamlined body, blubber also aids locomotion with regard to buoyancy. However, this depends on how it is stored on the individual's body and used when expending energy (Iverson 2009).

## Physiology

Locomotion is energetically more expensive when you compare cetaceans to fish. Because cetaceans are mammals, a large portion of their energy goes toward producing body heat. For an animal to thrive, there needs to be a positive balance between the costs of maintaining body functions and energy gained from food. The amount of energy cetaceans acquire depends on the type of food they ingest, which can vary between species and the environment they live in. Cetacean energetics can be elaborate, as there are many different factors to consider, such as energy needed for prey acquisition, thermoregulation, metabolism, activity, growth, repair, reproduction, and energy storage. Their bodies have specialized internal structures and mechanisms to utilize and conserve energy while in motion.

Cetaceans have a unique way of swimming by using lift-derived propulsion. Lift is the force that acts perpendicular to the flow of fluid against an object (Hall 2015). The flukes act as a flexible hydrofoil to facilitate lift, and their shape affects how much thrust power can be gained from a

stroke and how much energy it will cost the animal (Fish 1998). An aspect ratio can be calculated to show how hydrodynamically effective flukes are (Fish 1998). As mentioned earlier in this chapter, the shape of flukes varies between species. The flukes of species with a high aspect ratio are long and narrow which enable the animal to propel themselves more effectively through the water. This is because they are able to generate a larger amount of lift while expending a small amount of energy with less drag acting against the movement. Therefore, slower swimming cetaceans such as the Amazon River dolphin (*Inia geoffrensis*) are found to have shorter, wide flukes with a low aspect ratio (Fish 1998). To swim forward, tail flukes oscillate up and down; both upward and downward strokes produce a great amount of thrust (Fish 1993). This undulating movement takes place mostly in the last third of their body, however, minimal movement can be seen at the front of the body with the rostrum moving upward simultaneously with the flukes. The amplitude of the undulatory wave of motion increases as it travels down the body (Skrovan et al. 1999). The type of swimming in which undulations occur mainly in the tail end of the body is called thunniform swimming (also carangiform swimming with a crescent shaped tail) (Fish and Rohr 1999). At the base of the flukes, a joint allows them to be pitched around an axis to change the angle of the directed force of each stroke (Fish and Rohr 1999). Longitudinal hypaxial and epaxial muscles connecting to the dorsal and ventral side of the spine are the main muscles used for propulsion. Vertebrae in the tail and trunk portions of the vertebral column have particularly long spinous and transverse processes to help with muscle attachment. They enhance muscle power output by acting as a lever to amplify swimming mechanics (Fish and Rohr 1999). Frequency of propulsive strokes depends on the size of the species and how fast they are swimming. Larger species of cetaceans have a lower stroke frequency compared to smaller species (Williams 2009).

During the majority of their daily activities, cetaceans spend time down in the water column

and often dive deep to forage. They have evolved to facilitate seemingly effortless dives while combating body drag and hydrostatic pressure. When humans dive underwater, we quickly feel changes in the small pockets of air in our sinuses and ears from the weight of the water above us. Since air is compressed with increasing depth, buoyancy of a marine mammal at depth is greatly affected. Cetaceans are able to dive so efficiently because their buoyancy decreases as they swim deeper due to the compression of their lungs (Skrovan et al. 1999). This influences their energetics and mode of swimming. During a deep dive, they modify their swimming behavior (gait) at different depths to accelerate in the most adept way (Skrovan et al. 1999). At the start of their descent, they use repeated strokes until they meet a certain depth, then switch to gliding. This change in gait is due to the reduction in buoyancy when their lungs begin to collapse. Therefore, the deeper they travel, the longer they glide (Skrovan et al. 1999). During a dive, oxygen stores in the lungs, blood, and muscles are consumed. A remarkable adaptation for diving is the high amount of myoglobin, an oxygen binding protein, cetaceans have in their muscles. Species that have a larger body mass with higher numbers of myoglobin are able to stay down for longer periods of time (Noren and Williams 2000). Another physiological occurrence observed in cetaceans is a decrease in heart rate (bradycardia) during dives, even when compared to their resting heart rate. However, it could be possible that their heart rates can be modified during a dive to manage oxygen consumption (Noren et al. 2012). When deep divers are ready to ascend, they use a considerable amount of locomotor effort with strokes that have a large amplitude. As they rise, hydrostatic pressure lessens, their lungs begin to re-inflate, and they switch to a stroke-and-glide locomotor pattern as their buoyancy increases.

## Behavior

For many years, people have taken notice of cetaceans “effortless” swimming abilities. Their drag reduction properties and propulsive mechanisms

allow them to reach surprisingly high speeds underwater. Sprinting speeds for odontocete species can range between roughly 6.1 and 12.5 m/sec, with killer whales (*Orcinus orca*) at the top end of this range. For mysticete whales (suborder containing baleen whales), their sprinting speeds range from 4.1 to 13.3 m/sec (Williams 2009). Though swimming at top speed can be useful at times, such as when feeding, it can also be energetically exhausting. Cetaceans usually swim at a routine pace that is slower and considered more casual swimming, which varies remarkably less between species compared to their top speeds. Routine speeds for odontocetes range from about 1.8 to 3.6 m/sec, with beluga whales (*Delphinapterus leucas*) on the slower end. Mysticetes routine speeds range from 2.1 to 2.6 m/sec (Williams 2009).

Cetaceans need to come to the surface often to breathe air. This can be costly when traveling because energy is lost and higher speed is limited when resistance is encountered from another drag force created by surface waves. Therefore, cetaceans often swim more than half a body length below the surface to avoid wave drag (Fish 1993). They have also developed noticeable behavioral strategies for reducing the effects of drag and its energetic costs. When traveling at high speed, porpoising is one behavior that can help facilitate gas exchange in the most energy-conserving way (Weihs 2002). Porpoising is a behavior that is characterized by a series of fast ballistic jumps that occur in between hasty bouts of swimming not far below the surface (Fish and Hui 1991). It allows an opportunity for the blowhole to be exposed to air quickly enough for respiration, and, while above a certain speed, it is more energetically advantageous to move through air as opposed to water (Au and Weihs 1980).

Another behavior cetaceans perform to conserve their energy while swimming is drafting or swimming in formation. They travel next to and slightly behind one another without touching and receive swimming assistance from pressure waves created by other individuals (Weihs 2004). This type of behavior is especially significant for neonates and calves. When cetaceans are born, they must immediately begin swimming and thus need

to stay close to their mother for feeding and protection. To swim next to a highly experienced adult would be a considerably difficult task for a young dolphin with a small body and without fully developed muscles (Noren et al. 2008). To keep up with their mother's speed, calves align themselves in different positions around her that help make swimming easier for them. As the adult swims, the water in front of her is pushed forward by her motion, then water behind her moves forward to replace her body mass that was previously occupying the space. This is called the displacement effect. The calf profits by positioning itself in the forward moving water where it is able to "ride" next to mom in her pressure wave (Weihs 2004), which is also referred to as a slip stream. Another force that is acting to aid the calf when it is in a position beside its mother is the Bernoulli suction. When the two are swimming close to each other, water is accelerating as it moves through the small space between their bodies, which creates a drop in pressure and attracts them towards one another (Weihs 2004). There are three common positions in which calves swim with their mother. The first, neonate position, occurs shortly after the calf is born. It stays a few centimeters from its mother around her upper flank (Weihs 2004). As it gets a few months older, the calf swims in echelon position, located more to the side of its mother's flank near her mid-body (Weihs 2004). In this position, calves benefit greatly by having higher average swim speed, and less effort is needed for each swimming stroke. Also, they are often observed gliding in this position, which rarely happen when young calves are swimming independently (Noren et al. 2008). When the calf gets larger its mother will need to expend more energy to support it in echelon position. Around a year of age, the calf has become a more experienced swimmer and its mother will encourage it to swim below her tail section with their head near mom's abdomen in infant position (Noren et al. 2008). Though this position has fewer hydrodynamic benefits compared to neonate and echelon position, the calf continues to prosper from close proximity to its mother's milk supply and an easy place to hide from predators

(Noren and Edwards 2011). All calf positions aid in their survival, as it gives them the ability to stick close to their mom while she is constantly on the move while foraging, socializing, traveling, and avoiding predators.

Similar to formation swimming and drafting, cetaceans are also known to ride in pressure waves created by other vessels. Bow-riding is one common behavior that has been observed in many odontocete species (but not all). Dolphins will ride the waves that are produced from the forward motion of a boat at high speeds which stretch outward from the bow and stern (Williams et al. 1992). Relative to the boat, they can hitch a ride at many distances, depths, and in different body positions and postures (Fish and Hui 1991). Individuals will benefit from utilizing this behavior to conserve energy when they are traveling at a fast pace. Compared to free swimming, bow-riding individuals will experience lowered heart-rate, respiratory rate, and blood lactate because the demands of swimming with aid are far less than without it (Williams et al. 1992). Cetaceans are also able to use naturally created waves from wind or surf to catch a ride. Instead of pressure waves, they use the energy produced by the wave at a particular slope and distribute their weight accordingly, the same way we would if we were trying to surf (Fish 1993). Although these riding behaviors are energetically advantageous for traveling, it has also been suggested that they occur as a form of play (Wursig 2009).

## Conclusion

Cetacean ancestors were once land mammals who eventually returned to the water, unlike fish whose ancestors have always lived in water. Considering this "shorter" amount of evolutionary time, cetaceans are capable of extraordinary locomotor abilities. They are some of the most efficient swimmers on the planet, aided by their morphology, a major adaptation to aquatic life. A fusiform shape and streamlined features greatly reduce resistance they encounter while moving in water. Along with their streamlined body, a hallmark of

cetacean locomotion is their physiology. Their body is designed to use lift-based thrust to propel themselves continuously through the whole stroke cycle with great power. During deep dives, they are able to adjust their swimming patterns to control for changes in hydrostatic pressure, and their internal organs are adapted to maximize dive duration by conserving oxygen in various ways throughout the dive. Finally, cetaceans have several behavioral tactics to reduce the work needed for swimming, by catching a free ride from pressure waves created by others and sea-faring vessels. All of these unique components of their body plan and clever behavior manifested from evolutionary adaptations to living in water and ultimately reduce their cost of locomotion.

## Cetacean Morphology

Stefan Huggenberger<sup>1</sup> and Bruno Cozzi<sup>2</sup>

<sup>1</sup>Department II of Anatomy, University of Cologne, Cologne, Germany

<sup>2</sup>Department of Comparative Biomedicine and Food Science, University of Padova, Legnaro, PD, Italy

Cetacea (whales, dolphins, and porpoises) are mammals fully adapted to life in water so that some typical mammalian traits are not visible from their exterior appearance. The body of cetaceans is streamlined in shape. The head is connected to the body without a distinct neck so that it is merged to a single unit. The large boneless caudal fin (fluke) as the actual organ of locomotion is an evolutionary innovation. It is horizontally orientated and not vertical as in fishes or ichthyosaurs. Accordingly, spine and trunk muscles of cetaceans are designed primarily for dorsoventral movements. Moreover, a boneless connective tissue formation represents the unpaired dorsal fin. Flippers (forelimbs) and dorsal fin only control and stabilize the body's position while swimming.

### The Origin of Modern Cetaceans

At the end of the last century, the knowledge about cetacean fossils was so sparse that one could not be sure what the ancestors of the cetaceans looked like. During the last 25 years, however, the topic has played a decisive role in the field of evolutionary biology. Today, it is certain that cetaceans belong to the same order (Cetartiodactyla) of even-toed hoofed animals (formerly classified alone as Artiodactyla) (Perrin et al. 2009). The ancestors of cetaceans were land mammals that lived about 60 million years ago. Their close relationship with the artiodactyls is clear from molecular studies that indicate that the cetaceans are closely related to the hippos (Hippopotamidae) (Price et al. 2005). The monophyly of the Cetacea is well established by morphological and molecular biological

characteristics. The traditional systematic classification in toothed whales (Odontoceti) and baleen whales (Mysticeti) is well secured.

On the morphological level, fossil findings of nearly complete skeletons revealed that the ankle joint (hock) of middle-Eozän Archaeoceti were clearly like that of even-toed ungulates since they had a talus bone (Astragalus) of the typical double-pulley form, an autapomorphy of Artiodactyla. Further characteristics (apomorphies) of cetartiodactyls are the par-axis extremities and the fibroelastic type of penis with a proximal sigmoid flexure. In comparison with the hippos, cetaceans share a multilocular (multichamber) stomach system, the nearly hairless skin, and the structure of the larynx entrance (Frey et al. 2015).

The Cetacea derived from the Mesonychidae, a group from the main line of ungulates († condylarths) in the Paleocene. From them the archaeocetes emerged in the lower Eocene, about 50 million years ago, as the earliest group adapted to the aquatic lifestyle. Probably due to their endothermy it was possible for the archaeocetes to populate all sea habitats and large river systems regardless of the ambient temperature. Because of the higher oxygen content of air in comparison to water, oxygen uptake via lungs is more effective than respiration by gills. This was another advantage for the evolution of these agile giant forms in the water.

### Outer Appearance and the Head

The sizes of cetaceans range from approximately 1.25 m of length and 25 kg weight for the La Plata dolphin (*Pontoporia blainvillei*) up to a length of 33.5 m and 190 t for the blue whale (*Balaenoptera musculus*). Despite this size range, solid compact bones are no longer necessary in cetacean due to the buoyancy of water. The main skeletal elements are cancellous bone, which are lighter, more flexible, and also more intense circulated by blood. Cartilage tissues have similar hydrostatic properties that would explain why cetaceans tend to have more cartilaginous skeletal elements in comparison to terrestrial mammals. Even fat is, in addition to its function for energy storage, found within the

cetacean skeleton to replace solid bone tissue. Due to their densities, the combination of these three tissues – bone, cartilage, and fat – may thus contribute to a balanced buoyancy of the cetacean body in water.

In comparison to terrestrial mammals, the skull of cetaceans shows three fundamental changes: (1) a far forwardly projecting bony rostrum, (2) shifts in the nostrils to vertex of the skull, and (3) deformation and rostrocaudal shortening of the skull. The rostrum and mandible are responsible for the typical form of the cetacean head. Many dolphins have long and narrow beaks, although some species show a more globose shape of the head. The mouth of baleen whales is huge in relation to body size.

In the cranium, the individual skull roof bones slide over each other (telescoping). The most shortened skull elements are the nasal and the frontal bones, while the parietal bone is deformed. The occipital bones become the largest elements of the neurocranium. They are very high, nearly perpendicular, and constitute the caudal part of the skull. Due to these modifications, the nasal passages are nearly vertical so that the blowhole is situated at the highest point of the head. Accordingly, it appears first at the water surface when dolphins surface. When breathing, cetaceans do not need to interrupt their natural swimming movements, which is highly energy saving.

The long mouth of baleen whales houses the filter apparatus of baleens in the upper jaw. This probably brought the recent baleen whales a decisive advantage in the food network of the oceans. Baleens are keratin plates arranged in parallel to form a weir system in the whale's mouth. In this way, they "filter" large quantities of plankton (mainly crustaceans) and smaller fishes from the water (Fig. 1). Thus, baleen whales are, although they feed on small animals, "grazer" rather than carnivores. This concept of diet and the baleen weir system was so successful in evolution that the representatives of the baleen whales became the largest animals living on our planet. The blue whale is the largest animal that ever lived. The fact that the ancestors of the recent baleen whales had teeth can be recapitulated by the discovery that the teeth are developed as anlage in the baleen whale fetus but are not visible in the newborn.

The sister group of the baleen whales, the toothed whales, developed a different strategy during the course of evolution to hunt for their prey. By the use of an echolocation system (an active bio-sound navigation and ranging system, bio-sonar), they hunt for larger prey items (in relation to their body size) than the baleen whales. Toothed whales actively emit click sounds, and the echoes are perceived by the animal and converted into an "acoustic image" of the environment. Thus, toothed whales can navigate

**Cetacean Morphology, Fig. 1** Schematic cross section (a) and lateral view (b) of the head of a bowhead whale (*Balaena mysticetus*). When swimming, water (blue

arrows) flows into the mouth frontally and out through the baleens. Prey items are filtered by means of the baleen system and can then be swallowed regularly

and locate fish and squid in total darkness with the echolocation system. In order to catch their fast prey, the agile carnivores are usually much smaller than the great baleen whales and, in case of many dolphin species, capable of acrobatic performances. The largest representative of the toothed whale, the sperm whale (*Physeter macrocephalus*), however, has found its ecological niche in the deep sea. It hunts in the Mesopelagial zone, often far more than 200 m (and often much deeper than 1000 m) below sea level. The same is true for another group of large toothed whales, the beaked whales. Sperm and beaked whales stay on the surface or close to only for the time required to supply with the vital oxygen and to recover from their hunt excursions into the depth. In order to locate the prey in these extreme depths, the echosounder of the sperm whales reaches over several hundred meters. In comparison, however, in the dolphins it only works successfully in the near area (up to approximately 115 m). No other species hunts in the oceans or other aquatic environments with the help of echolocation.

To catch their prey, toothed whales use their jaws mostly equipped with many polyodont and homodont teeth (meaning that they have many teeth, all of the same dimension and shape). The teeth in the maxilla and mandible, up to 260, are usually cone shaped. There is only a single dentition. Some toothed whale species such as the beaked whales do not have teeth or only a single pair. All toothed whales suck in the prey by the help of their strong gular and hyoid musculature and swallow it whole. Due to the short neck region, which contributes to the streamlined body contour, the hyoid bone is very close to the sternum.

The base of the cetacean skull is characterized by bony structures responsible for hearing. The ancestors of all recent whales already showed adaptations for hearing underwater. The archaeocetes showed ear bones almost completely detached from the skull. The achievement of advanced hearing underwater requires a reduced mastoid process that allows disconnection of the ear bones from the skull and was found in both baleen and toothed whales since the Oligocene (around 30 M years ago). As a result, the middle ear and inner ear structures could vibrate freely from the rest of the

skull and thus improved directional hearing underwater. Toothed whales have, additionally, specialized fat bodies in the mandibles that couples acoustically the surrounding water to the ear bones.

The tiny middle ear ossicles of the hammer, anvil, and stirrup are enclosed in a bony capsule at the base of the skull. The three middle ear ossicles, a unique mammalian trait, represent an effective filtering and amplifying system unknown in other aquatic vertebrates. The audible range of dolphins includes an extensive spectrum from sonic low frequencies below 20 Hz to the ultrasonic range up to 280,000 Hz. Mainly the ultrasonic frequencies are used for their echolocation system. Baleen whales communicate with infrasonic and sonic frequencies because these long sound waves may travel over very long distances (hundreds of kilometers) underwater.

A prerequisite for echolocation of toothed whales is, next to a fine-tuned hearing system, a loud "voice." For the echolocation click sounds, a hypertrophic complex in the nose of these animals evolved to generate, emit, and focus sound underwater without any significant loss of energy. Thus, dolphins and other toothed whales generate the sound in the nose and not, as usual in other mammals, with the larynx. In the sperm whale, the nose is particularly impressive: the nasal complex degrades the skull to an insignificantly small structure. The skull of 18 m large sperm whale bull is almost 6 m long. It forms a long "armchair" in which the nasal complex is located (Fig. 2). This nasal complex is formed primarily by two huge fat bodies so that more than a quarter of the total weight of the sperm whales is due to the weight of the nose. Sperm whales generate the loudest sound in the animal kingdom with their nose, up to 236 dB re. 1  $\mu$ Pa which, in theory, would yield 205 dB in air.

### The Brain

Dolphins (and to a certain extent whales) have relatively large brains for their body mass, similarly to apes. The cetacean brain is wider and shorter than the brain of a terrestrial mammalian brain of the corresponding mass, due to the modifications of the cranial cavity. The transition from a terrestrial to the aquatic lifestyle changed the proportional relationships of various parts of the

**Cetacean Morphology,**

**Fig. 2** Right lateral view of the head of the sperm whale. The structures of the nose, i.e., the nasal fat bodies (yellow), are extremely prominent. The air connecting system (nasal passages and adjacent air sacs) is depicted in purple

**Cetacean Morphology,**

**Fig. 3** The brain of the beaked whale (*Hyperoodon ampullatus*) from below (ventral view). Note that the neocortex is massively folded showing a complex pattern of gyri and sulci. I, olfactory nerve; II, optic nerve; VIII, vestibulocochlear nerve (Adapted from Kükenthal 1893)

brain. With the acquisition of echo-orientation, the acoustic pathways became the absolute dominant part of the brain. In parallel, cetaceans have a hypertrophied cerebral cortex with a strongly developed groove pattern (gyrification) (Fig. 3). However, the gray matter of the neocortex is thinner than in humans with only about half number of neurons in case of the bottlenose dolphin (*Tursiops truncatus*).

The structure of the cetacean neocortex follows the bauplan of terrestrial Cetartiodactyla, i.e., the functional units (cortical columns) of most areas exhibit five cortical layers (primates and rodents generally show six layers) composed of different neuron populations with characteristic features as to size and shape of perikaryon as well as the arrangement and local distribution of their

processes. In general, the dolphin neocortex is dominated by large- and medium-sized pyramidal neurons. Whereas there is a layer IV in every primary sensory area in the human, the situation in dolphins is reverse. Adult dolphins show only more or less discontinuous residues of layer IV in a restricted area of the primary visual cortex. In all primates, layer IV is the main termination of thalamo-recipient fibers. Furthermore, layer IV is particularly conspicuous in the primate association areas of the frontal cortex. However, a distinct layer IV does not exist in cetaceans, as in Perissodactyla and terrestrial Cetartiodactyla. Several hypotheses have been forwarded to explain the functional circuitry and projections of a five-layered cortical column. Most of them, however, are based on the model of the agranular human

motor cortex (in which layer IV is limited or absent), and so their applicability to whales and dolphins remains to be verified.

The two cerebral hemispheres are connected by a relatively thin corpus callosum. Interestingly, during sleep periods, only one brain hemisphere is awake and controls the body, while the other hemisphere rests. Sleeping is probably rare in cetaceans, and there are only about 3–5 min continuous sleep interrupted by pauses of breathing.

In toothed whales, the various cortical and subcortical components of the limbic system show different degrees of development. The hippocampus and the mammillary body are extremely reduced and interconnected by a relatively thin fornix. The anterior thalamic nuclei and the habenulae, however, are further developed than in other mammals. In contrast to the nucleus of the olfactory tract, the amygdala complex is well developed in microsmatic species (baleen whales) and in anosmatic species (toothed whales). This indicates that, apart from olfactory stimuli (see below), input to the amygdala arises from other sources, among them the auditory system. Furthermore, the remarkable development of the cortical limbic lobe (periarchicortex), and the specific paralimbic lobe, also points to the largely nonolfactory character of this system in the dolphin (Cozzi et al. 2017).

## The Sense Organs and Cranial Nerves

As seen for the hearing system and the toothed whale nose, aquatic life placed very different demands on the mammal-specific sense organs of cetaceans. Here, because of the nasal sound generation, toothed whales have reorganized their whole nasal system so that they do not develop an **olfactory** epithelium. In general, toothed whale embryos display the anlage of an olfactory bulb which, however, completely disappears in the subsequent fetal stages. Thus, adult toothed whales do not have an olfactory mucosa or an olfactory nerve and bulb. A vomeronasal organ is also absent in cetaceans.

Adult baleen whales still have a small but functional nose equipped with an olfactory

nerve, an olfactory bulb, slender olfactory peduncle, and an olfactory tubercle, a situation resembling that of many terrestrial microsmatic mammals. Interestingly, the functional significance of the detection of airborne odors for an animal living in the oceanic environment is not clear.

Dolphins are clearly sensitive to chemical stimuli but most cetacean species have no taste buds. Since the olfactory part of the nose was completely reduced, dolphins may relay probably on the trigeminal innervation of the oral cavity for chemoperception (Oelschläger and Oelschläger 2009). The trigeminal nerve is the thickest cranial nerve in baleen whales but the diameters of the axons tend to be thin. In the smaller toothed whales so far investigated, the trigeminal nerve contains 82,000–156,000 axons (human: 140,000). The trigeminal nerves in the large whales have 400,000–500,000 axons. This high number of axons may be explained by the extreme size of the forehead region innervated in these animals. However, the sense of touch was reported to be insignificant in cetaceans although the skin is richly innervated around the mouth, the blowhole, and the genitals.

Cetaceans have laterally placed **eyes**, and a binocular visual field is present only in small species (including most dolphins) and limited to a reduced rostral and ventral area. Other possible reduced fields are placed dorsally and slightly caudally. However, the sense of sight may play only a minor role underwater; the eyes of cetaceans, except some river dolphins, are reported to be fairly well developed and equipped with a spherical lens. With this spherical lens, a sharp image on the retina may be produced in low-light conditions underwater as well as in air in bright-light condition. Both eyes can be moved individually. In the bottlenose dolphin 147,000–390,000 axons were found in the optic nerve compared to 1,200,000 in the human. In baleen whales, the optic nerve may contain approximately the same number of axons as in the bottlenose dolphin, whereas in the sperm whale only 172,000 axons were counted.

Dolphins have a thick retina comprised of rods and cones. The fovea centralis (area of best visual

resolution) is band shaped, and the neurons in the ganglionic layer are very large (up to 150  $\mu\text{m}$  in diameter). The optic fibers show a complete or almost complete decussation.

Electrophysiological mapping studies in dolphins have located the visual cortex not in the dorsocaudal or occipital part of the hemisphere as in most mammals but in a more central position near the midline.

The **auditory system** in the brain of whales and dolphins corresponds to that in terrestrial mammals but shows a significant increase in size. According to the impressive diameter of the vestibulocochlear nerve, i.e., the number of fibers of its cochlear part, the all auditory nuclei are very large in cetaceans. And, thus, the secondary auditory fiber tracts (trapezoid body, acoustic striae) are well developed.

A comparison between relative volumes of other auditory nuclei in the common dolphin and the human is impressive. There are multiples for the dolphin cochlear nucleus ( $16\times$ ), lateral superior olive ( $150\times$ ), nuclei of the lateral lemniscus (up to  $200\times$ ), inferior colliculus ( $12\times$ ), and medial geniculate nucleus ( $7\times$ ) (Oelschläger and Oelschläger 2009).

In general, auditory structures are smaller in baleen whales than in toothed whales. The components of the midbrain tectum differ in size in baleen whales and toothed whales. In most baleen whales, the inferior colliculi (audition) are smaller or as large as the superior colliculi (vision). Toothed whales have very large inferior colliculi. This fact demonstrates the dominance of the sense of hearing in toothed whales and the importance of their echolocation system. The auditory system shapes the morphology, size, and connectivity of the whole toothed whale brain due to the necessity of processing vast amounts of acoustic information and the high propagation velocity of sound in water. Toothed whales scan their surroundings with their echolocation system constantly and additionally communicate by the help of the various vocalizations. Accordingly, they have extended neocortical auditory projection fields in comparison to other neocortical areas.

The diameter of the vestibular nerve is only one-tenth that of the cochlear nerve, a fact that

correlates well with the very small semicircular canals and the low number of vestibular ganglion cells in toothed whales.

## Skin

The structure of the skin and blubber of cetaceans is highly organized and complex. It was described to have a smooth rubbery texture without glands. The epidermis of cetaceans is characterized by the lack of keratin and by a prominent interdigitation of epidermal rete pegs and long dermal papillae. The thickness of the epidermis varies depending on species, age, and location sampled between 1 and 10 mm in mean. The ventral body wall tends to have the thickest epidermal layer.

The dermis and subcutis join to the thick blubber layer which is multifunctional. It is the primary site for metabolic energy storage, provides thermal insulation, and contributes to positive buoyancy. The blubber also functions to streamline the cetacean body and to form specialized locomotor structures such as the dorsal fin, propulsive fluke blades, and caudal keels. Construction of the blubber structures relies not only on lipid but also on the fiber equipment of collagen and elastin.

There is a plexus of parallel running arteries and veins in the fluke, dorsal fin, and flippers. Here, thick and muscular walled central arteries are surrounded by a plexus of veins running alongside and function like a heat exchanger to regulate body temperature.

Toothed whales possess shallow, regular cutaneous ridges of the surface of the skin over much of their bodies. They are usually faint and can be seen by close inspection of the skin of a living animal at an oblique angle. These ridges are generally quite shallow at the surface (less than 10 to slightly over 100  $\mu\text{m}$  high) and range in width from 0.4 to 1.7 mm in dolphins.

## Respiration, Circulation, and Diving

The oxygen uptake of cetaceans is very effective. They can exchange about 75–90% of the air

volume in the lungs with each breath (land mammals about 10–15%). To dive, oxygen is mainly in body tissues, in particular in the muscle, which is rich in myoglobin. Although the stored blood oxygen content is relatively low, the blood represents an important oxygen storage because dolphins have two to three times greater relative blood content per kg body weight (120–180 ml kg<sup>-1</sup>) as terrestrial mammals. When diving, the oxygen consumption is reduced. Cardiac activity and blood circulation slow down, and some organs can be temporarily separated from the oxygen supply.

For respiration air is rapidly exhaled first when surfacing, which happens with a loud blow because air is blown under strong pressure through the narrow nostrils. The cooled and depressurized air may condense into a cloud of fog called “the blow” in large whales. After exhaling, the inhalation follows immediately. The entire respiratory exchange lasts less than a second in dolphins and can be repeated after a longer dive several times. The diving duration varies depending on the species and situation. Many dolphins usually dive only for a few minutes, while sperm whales and beaked whales can stay submerged well over 1 h without surfacing to breathe.

How the dolphin’s body rules the pressure at great depths remains a mystery in many ways today. Since oxygen is mainly bound to body tissues, cetaceans need little air in their lungs while diving. The cetacean lungs are relatively small; their wall is stabilized up to the level of the entrance to alveoli with cartilage rings. During deep dives, the lungs must collapse almost completely similarly to the bellows of an accordion and pressed to the thoracic spine and ribs. Other organs (except the air-filled middle ear) are generally rich in water and fatty liquids and thus are nearly incompressible. Therefore, they can withstand the intense pressure. Arteries with increased muscular walls form widely branched meandering systems, called *retia mirabilia*, fill out many cavities of the body like thick cushions. These *retia* may control blood pressure when the water pressure is changing. Probably they also prevent the formation of gas bubbles in the

blood during rapid emergence and thus reduce the risk of decompression sickness.

## Inner Organs

The main distinctive feature of the digestive system of cetaceans is the presence of a multi-chambered stomach. In dolphins, the stomach has three sections that continue with a pyloric chamber. The first section is the fundus, which is responsible for the storage and mechanical processing of food. It is followed by the main body of the stomach and the pyloric stomach, both draining their digestive glands. Most beaked whales have five stomachs; other cetacean species possess even more chambers. Small intestine and colon can be distinguished from each other only histologically. The relatively large liver has no gall bladder.

The kidneys show a grape-like structure with up to 10,000 lobules (renculi) in the large whales. Interestingly, similar features can be found in the human fetus and in bovine.

From the skeleton of the hind limbs, only small **pelvic** rudiments inside the body are present in dolphins where the strong penis musculature or the vaginal muscles originate. The testes are intraabdominal and moved far dorsally just behind the kidneys. The fibroelastic penis is to a large extent within the abdominal cavity between the pelvic bones. It runs in an S-shaped curve into a longitudinal belly fold, which opens with a narrowly elongated slit caudally of the umbilicus. The apical portion which is located in the penis fold is only superficially comparable to a glans penis, since there is no independent corpus spongiosum. For erection, the penis straightened because of the blood filling the unpaired corpus cavernosum and also because the two parallel retractor muscles (that keep the S shape of the organ at rest) relax.

The female reproductive organs are shifted dorsally. The uterus has two horns and the embryo usually develops only in the left uterine horn although the placenta partially extends into the contralateral horn. The vagina opens into an elongated fold, which lies directly in front of the anus.

There are only fragmentary information and estimates about the reproductive biology of most cetaceans. In many whales, both sexes show a seasonal reproductive cycle, and the seasonal increase in activity of the testes in the males is linked to the estrous cycle of the females. Most cetaceans are promiscuous.

The gestation periods are generally long in cetaceans. In dolphins, it varies depending on the species between 9 and 17 months, although it is not necessarily correlated with the body size of the animals. Twin pregnancies are very rare. The birth takes place tail first, as breech birth, but the head position is also possible. In any case, the newborn must be quickly brought to the surface so that it can take its first breath.

The newborns are fully developed and reach about one-fifth of the length of the mother. Thus, they are comparable with advanced precocial birds or running hoofed mammals. A correspondingly high birth weight is made possible because the birth canal can greatly expand due to the rudimentary pelvic bones. In some species, infants are tended not only by the mother but also sometimes by several “aunts.” Since cetaceans do not have absorbent lips during lactation, the teat is taken into the mouth, and the milk is ejected by the mammary gland by muscle actions. The two mammary glands are on either side of a line between the umbilicus and the vaginal slit. Lactating *mammas* may be swollen, so that the otherwise hidden teats slightly protrude outward. The milk is extremely nutritious (fat content 16–36%, only about 5% for most land mammals) and facilitates fast growing. Nevertheless, the young dolphins are breastfed unusually long, from several months up to 8 years (bottlenose dolphin). Calving intervals range from 1 year in the smaller dolphin species to 8 years in killer whales. Sexual maturity is reached in the small species (i.e., the common dolphin) within 6 years and up to 16 years in killer whales.

## Definition

The process that mysticetes and odontocetes employ to move from one place to another, often by determining one's position over time and space.

## Introduction

Animals that dive to great depths or migrate long distances in the open ocean must employ a wide variety of methods to navigate their environment. Navigation techniques sometimes differ by species, and likely include a combination of sensory systems depending on the situation and perception cues available. There is still much to uncover about the mechanism of each sensory modality used for navigation by cetaceans. Because of the difficulty of experimenting on large cetaceans, many inferences about the mechanisms of cetacean navigation have been made from studies conducted on sea turtles, birds, and small odontocetes. Experiments on captive odontocetes have informed discoveries on sensory modalities used with echolocation and magnetoreception. Bio-logging techniques on wild populations have revealed information on the use of geomagnetic, visual, and passive acoustic cues for long-distance migration. Although there are other sensory modalities used by cetaceans (e. g., chemoreception, somatosensation, electroreception, balance) (Torres 2017), we have reviewed the literature for each sensory modality as it relates to cetacean navigation and describe the most commonly documented methods below, including acoustic, visual, geomagnetic cues, and cultural transmission.

## Acoustic Cues

In the marine environment, sound plays an important role in navigation. Sunlight is rapidly attenuated with depth and in turbid water. Even where light is available, it can be difficult to see to equivalent distances compared to in-air environments. Sound, however, travels roughly five times faster in water than in the air, and low frequency sounds can propagate many miles (Payne and Webb 1971). As a result, sound is the primary sensory cue for cetaceans interacting with their environment.

Toothed whales, dolphins, and porpoises (odontocetes) have developed highly sophisticated echolocation systems to sense their

surroundings. Similar to man-made sonar, an echolocating odontocete sends out packets of short-pulsed high-frequency sounds ranging from 40 to 150 kHz. When the directional sounds hit an obstacle, they bounce back to the animal's lower jaw, allowing the odontocete to discriminate among items, localize in three-dimensional space, and estimate distances to other animals, objects, the seafloor, and the surface (Au 1993). While echolocation has been extensively studied for its use in sensing and capturing prey, it also assists cetaceans in navigation. Wild finless porpoises (*Neophocaena phocaenoides*) inspect upcoming areas up to 77 m away with regular echolocation clicks before they swim silently at ranges closer than 20 m (Akamatsu et al. 2005). Large inspection distances have been documented for wild and captive bottlenose dolphins (*Tursiops truncatus*) that use echolocation up to 140 m and 113 m, respectively (Au 1993). These and other odontocetes use echolocation to first establish an understanding of their environment at greater distances before engaging in short-distance foraging-related echolocation.

Baleen whales, or mysticetes, do not possess the anatomical structures that odontocetes have for active echolocation. However, they can listen to the returning echoes from their own vocalizations to gain information about the environment (Payne and Webb 1971). One example of a mysticete that uses passive listening to navigate its environment is the bowhead whale (*Balaena mysticetus*). Bowheads migrate annually between their summer feeding areas in the Beaufort Sea and winter breeding areas in the Bering Sea, spending most of their time beneath sheets of ice. They create breathing holes by breaking through areas of thin ice with their large heads. This requires a mechanism for assessing ice condition to determine if ice is thin enough to break through. To do this, bowhead whales use the relative level of echoes from their frequency-modulated calls bouncing off the ice (Ellison et al. 1987). They typically target ice less than 20 cm thick, but can break through ice up to 60 cm, while actively avoiding multiyear ice floes 10–20 m thick. By using this passive

listening mechanism, bowheads are able to navigate safely beneath Arctic ice sheets.

Passively listening to external sounds may provide additional details about environmental surroundings. The source of these external acoustic cues may be biotic (biological) or abiotic (nonbiological). There are many sources of biotic sound in the ocean, including social sounds made by members of the same species. For example, humpback whales (*Megaptera novaeangliae*) form and maintain acoustic herds similar to terrestrial herds that are maintained by visual contact (Payne and Webb 1971). This species-wide acoustic behavior may have evolved in response to the extensive 12,000-mile migration between winter breeding grounds and summer feeding grounds. Acoustic herds have been detected outside breeding grounds along migration routes, and therefore can be used by humpback whales to find, join, and remain within migration corridors (Norris et al. 1999). Propagation models have also suggested that the 20-Hz sounds produced by fin whales (*Balaenoptera physalus*) should be audible to ranges of 525 miles if propagating within the deep sound channel. This allows fin whales, who lack fixed breeding regions, to come together at will by maintaining an acoustic herd over their entire distribution range (Payne and Webb 1971).

Other biotic noise generated by snapping shrimp, fish, invertebrates, and abiotic sounds like relative levels of surface and benthic noise, may serve as landmarks for migrating whales. These soundscapes can indicate proximity to land, relative depth, and even substrate type. Shore noise, which generates sounds within 100–1000 Hz, falls within the ideal inferred hearing range of baleen whales. Western gray whales (*Eschrichtius robustus*) have some of the longest known migrations of any cetacean, and are able to maintain their coastline routes by keeping the sound of the surf to one side, especially in more bathymetrically complex portions of the coast (Mate and Urban-Ramirez 2003). Because grey whales remain close to the shoreline while migrating, they likely combine these acoustic cues of the breaking waves with in-air visual cues of the coastline itself.

## Visual Cues

Given the highly specialized hearing and echolocation abilities of cetaceans, vision would seem to be of less importance when it comes to navigation. However, many cetaceans spend a substantial proportion of their lives in well-lit shallow waters, where underwater vision remains evolutionarily adaptive. The disproportionately large pupils of humpback whales collect large amounts of light, enabling them to see even in the deep ocean. Direct observation and experimental studies of dolphins in managed care have shown that dolphins have excellent in-air and underwater vision. Their visual acuity is better in-water than in-air, but the range for many species of cetaceans is comparable to terrestrial mammals. Cetaceans also have lateral vision, which can provide a 120–130° visual field (Kremers et al. 2016). As a result, both in-air and in-water vision are likely used by cetaceans to inspect their surroundings.

In shallower waters, where there is greater visibility from incoming sunlight, whales may use bathymetric features as visual landmarks to navigate. Humpback whales departing from New Caledonia display widely dispersed migratory paths with multiple routes. However, their migrations include multi-day stops at La Torche and Antigonina, two shallow seamounts off Australia (Garrigue et al. 2015). Seamounts, which are widespread throughout all ocean basins and irregular in size and shape, create distinct cues in the open ocean where there are few visual cues. Additionally, the complex three-dimensional habitats on seamounts host high densities of invertebrate and vertebrate species (Morato et al. 2010). This creates further visual distinction, which may also be assessed with other sensory systems using acoustic, chemical, thermal, or hydrodynamic cues. Seamounts also have distinct geomagnetic signatures, so whales may be using the magnetic field of seamounts to navigate as well (see *Geomagnetic Cues*).

All cetaceans must surface to breathe at regular intervals. A special surface behavior, called spyhopping, has been documented in both odontocetes and baleen whales. Rather than the

typical horizontal surfacing associated with normal respiration, spyhopping involves the animal lifting its head straight up and out of the water. Combined with their lateral vision, spyhopping allows cetaceans to inspect objects above the water, which may provide further orientation information (Kremers et al. 2016). Gray and humpback whales regularly display this behavior on their migration route. Mysticetes may spyhop to combine visual cues with acoustic cues of the surf break to remain oriented to the coastline (Pike 1962). Although dolphins do not usually engage in long-distance migration, they may use this and other surfacing behaviors such as porpoising to visually assess their surroundings (Madsen and Herman 1980).

The use of celestial bodies for navigational purposes is better understood in other species, including birds and bees. However, some hypothesize that cetaceans can visually orient with the sun, moon, or stars (Horton et al. 2011). Tagged humpback whales in the South Atlantic and South Pacific Oceans were found to travel along a straight path migration route (within 1° of precision) (Horton et al. 2011). The magnetism of the Earth varies too widely to attribute this ability by geomagnetic cues alone. However, the additional visual information gleaned from the position of the stars and the moon would allow these humpback whales to maintain straight-line trajectories. Therefore humpback whales may combine visual cues with geomagnetic compass mechanisms to navigate their long journeys (Horton et al. 2011).

## Geomagnetic Cues

Migrating animals like sea turtles and birds can sense and use the Earth's constant dipole magnetic field (Wiltshko and Wiltshko 2005). The geomagnetic intensity is highest (>60,000 nT) near the Arctic and Antarctic, and is lowest (<30,000 nT) in the tropics (Kremers et al. 2016). Magnetic disturbances caused by electromagnetic radiation from the sun (daily fluctuations), sun spot activity (irregular variations), or even local geology, such as iron-dense rocks, can alter the local magnetic field and create anomalies, disrupting

the otherwise reliable geomagnetic topography of the Earth (Wiltshko and Wiltshko 2005; Klinowska 1985). Therefore, a geological valley (area between hills or mountains) does not necessarily equate to a geomagnetic valley (area of low magnetic intensity) and vice-versa. A number of studies investigating the potential use of magnetoreception in navigation have found correlations among geomagnetic topography and some cetacean strandings (Kirschvink et al. 1986; Klinowska 1985). However, not all strandings result from errors in magnetoreception (Balcomb and Claridge 2001).

All documented live strandings of cetaceans in the United Kingdom over a 70-year period occurred in areas where the geomagnetic anomalies were very low and geomagnetic contours were perpendicular to the coast (Klinowska 1985). Another research group observed a similar relationship between beached cetaceans and areas with relatively low magnetic intensity on the east coast of the United States (Kirschvink et al. 1986). Yet another study found a link between mass sperm whale (*Physeter macrocephalus*) strandings in the North Sea and solar storms, which temporarily affected the Earth's magnetic field (Vanselow et al. 2017). Because cetaceans appeared to strand due to misguided orientation caused by geomagnetic topography or anomalies, researchers inferred that they must also use geomagnetic cues in normal circumstances (Klinowska 1985). This would be particularly successful in the open ocean where there are few landmasses and magnetoreception would be most adaptive. Reports of fin whales (*Balaenoptera physalus*) that were observed actively migrating in geomagnetic valleys support this hypothesis (Walker et al. 1992). In addition, offshore species of cetaceans such as false killer whales (*Pseudorca crassidens*) live-stranded more frequently than inshore species such as the harbor porpoise (*Phocoena phocoena*), indicating that geomagnetic cues may be more utilized and relevant to offshore cetaceans that may target areas of low magnetic intensity while traveling long distances in the open ocean (Klinowska 1985).

While growing evidence supports the use of magnetoreception by migrating mysticetes and

open-ocean cetaceans for navigation, causal relationships can only be established with experimental testing, controlled conditions, or (in the case of large and elusive species) longitudinal repeat tracking (Allen 2013; Walker et al. 1992). There are also many unknowns regarding the method(s) of geomagnetic navigation, its precise mechanism, and if inshore dolphins utilize it at all (Kremers et al. 2016). The simplest method of geomagnetic navigation, vector navigation, relies exclusively on directional information such as heading south in winter (Wiltschko and Wiltschko 2005). In true navigation, an animal possesses the compass from vector navigation and can sense the intensity and inclination of an area, which may be used to extrapolate relative position as on a map (Allen 2013; Wiltschko and Wiltschko 2005). To find out which method humpback whales used, one study compared the tracks of tagged whales migrating from Alaska to Hawaii to modeled tracks of bicoordinate geomagnetic navigation (Allen 2013). Most of the whales' routes matched the modeled tracks, suggesting that humpback whales use true navigation. However, this study's small sample sizes call for further investigation.

There are two main hypotheses regarding the precise mechanism behind cetacean magnetoreception. Perception based on induction suggests that because cetaceans live in such a conductive medium (i.e., salt water), they can detect magnetic fields through specialized electroreceptors (Wiltschko and Wiltschko 2005). Perception based on magnetite particles (i.e., iron oxide) in the skull suggests that the particles can align with the Earth's magnetic field and transmit this information through the central nervous system. Although the neurological pathways mitigating this connection are unknown, crystals of magnetic iron oxide have been found in the brains of humpback whales and in the membrane surrounding the brain and spinal cord of short-beaked common dolphins (*Delphinus delphis*) and bottlenose dolphins (*Tursiops truncatus*) (Bauer et al. 1985). If cetaceans can use magnetoreception, then it is possible that they have specialized mechanisms for both detecting magnetic intensity and mediating directional information (Wiltschko and Wiltschko 2005). It is also possible that they use

both induction and magnetite particles (Kremers et al. 2016).

It is still uncertain whether most odontocetes can use magnetoreception. An observational research project was not successful at identifying geomagnetic cue use in wild short-beaked common dolphins (Hui 1994). However, experimental studies on captive dolphins have found that respiration, electrocardio, and galvanic skin responses, as well as response time, alter in response to changes in a magnetic field or a magnetized object, respectively (Kremers et al. 2016). These results suggest that at least some species of odontocetes can discriminate stimuli based on their magnetic composition, a prerequisite for magnetoreception-based navigation.

## Cultural Transmission

While not sensory modalities, memory and learning through cultural transmission may be crucial aspects of cetacean navigation. Whitehead and Rendell (2015) define culture as information transfer among conspecifics. There is evidence that cetaceans have the ability to gain information about their surroundings over time and transfer this knowledge to one another (Brent et al. 2015; Whitehead and Rendell 2015). Information can be transferred many ways. Southern right whales (*Eubalaena australis*) migrate annually from Antarctica to New Zealand because they display a site fidelity preference encoded in their genes and/or learned about mating opportunities in warmer waters from other individuals (Whitehead and Rendell 2015). In the event of either (or both) of these scenarios, cetaceans shape the migration routes, memories, and navigation abilities of their decedents (Torres 2017). While many cetacean species are capable of cultural transmission, the most researched are bottlenose dolphins, killer whales (*Orca orcinus*), sperm whales, and humpback whales (Whitehead and Rendell 2015).

Cultural transmission has been observed through mother-calf, group-specific, and rapid-spread social learning. These three categories may be utilized together or alone based on the distance, age, gender, and/or social dynamic of

both the sender and receiver of information (Whitehead and Rendell 2015). Cetaceans have a fission-fusion society, where relationships between individuals are fluid. However mother-calf pairs have a very strong and stable bond, especially in the first several years of a calf's life. Humpback whale calves remain with their mothers far beyond the required 6 months of nursing, and will stay by her side at least until their first migration. As mothers lead their calves between warm-water breeding grounds and the cold-water feeding grounds, calves may begin to learn the route for themselves (Whitehead and Rendell 2015). This transmission of information from mother to calf may be reinforced with the addition of other sensory modalities, such as vision and magnetoreception. Using a combination of senses, calves may memorize the geomagnetic patterns, geographical shapes, and coastal landmarks year after year (Torres 2017). Similarly, beluga whale (*Delphinapterus leucas*) calves that complete initial migrations with their mothers continue to navigate the same route as adults (O'Corry-Crowe et al. 1997).

Even after young whales separate from their mothers, entire populations of migrating cetaceans will travel to equatorial breeding grounds at relatively the same time. Humpback whales were found traveling in small groups more often than not. Therefore, even if juveniles are not prepared for a solitary migration, they have the opportunity to learn how to navigate the open ocean from a group. Group-specific social learning can also be found in sperm whales that consistently displayed different traveling behaviors (i.e., heading, interanimal distance, and straight-line distance) between groups, but kept behaviors similar within groups (Whitehead 1999). The *many wrongs hypothesis* assumes that a larger group will produce fewer inaccuracies on their route, and that the older more experienced individuals will be making the bulk of the navigational decisions (Rozhok 2008). Post-reproductive killer whale matriarchs transferred ecological knowledge to group members by leading the group's collective movement through feeding grounds, especially in years of low prey abundance (Brent et al. 2015).

While mother-calf and group-specific social learning is usually passed down vertically from one generation to another, rapid-spread transmission occurs horizontally within generations (Whitehead and Rendell 2015). Examples include the transmission of novel methods of foraging (e.g., humpback lobtail feeding) and playing (e.g., southern right whale tail-sailing). Rapid-spread transmission also facilitates the homogenous whale song alterations from year to year, and therefore may help maintain humpback whale acoustic herds that aid in navigation (see *Acoustic Cues*).

## Conclusion

Similar to their use of multimodal sensory systems while feeding (Torres 2017), cetaceans likely integrate many sensory modalities to navigate through their environment. Acoustic, visual, and geomagnetic cues and cultural transmission are not the only methods cetaceans use to navigate, but are currently the most documented. There is evidence that humpback whales use the distinct change in temperature along coastal fronts to navigate (Reinke et al. 2016), and it is possible that unknown tactile methods and sensory modalities are being used as well. Inexperienced cetaceans may not have full control of their abilities, and must learn to use sensory cues to avoid getting lost or stranding during travel. They must also learn to adapt to naturally occurring environmental changes, such as the effect of solar flares on magnetoreception (Vanselow et al. 2017). Anthropogenic activities can further disrupt the mechanisms of navigation. For example, increased noise from ship traffic can mask acoustic cues (Erbe 2011), and climate change may force whales to change their navigation routes in search of food (Meyer-Gutbrod and Greene 2017). More research is needed to understand the four navigation techniques described herein, as well as other potential methods used for navigation. This will be especially important for conservation as managers seek to mitigate threats to endangered and threatened cetacean species.

humpback whale, *Megaptera novaeangliae*) and the odontocetes (the toothed whales, such as the bottlenose dolphin, *Tursiops truncatus*). These two groups have very different ecological niches, spatial and temporal distribution patterns and social structures, and this is reflected in their very different sensory capabilities. In addition, as several species of odontocetes can successfully be kept in captivity, it is for these species that we have the greatest understanding of sensory systems and abilities. The most information is available about vision and hearing; the other senses (chemoreception, balance, somatosensation, electroreception, and magnetoreception) have received comparatively little attention.

## Vision

Cetaceans appear to use vision in a variety of contexts (e.g., communication, prey capture), and cetacean vision relies on the same structures and principles as vision in terrestrial mammals. Light enters the eye and is refracted by a lens and cornea onto the retina, which contains the sensory cells of the eye (the rod and cone cells) (Kröger and Katzir 2008). Underwater vision is constrained by several factors however. In general, light levels in the aquatic environment are reduced due to scattering by particulate matter and high levels of absorption. Light absorption is wavelength specific; red light (~650 nm) is absorbed very quickly, while blue light (~475 nm) has the least absorption and therefore has the deepest depth of penetration (Kröger 2008). The refractive index of water is very different from air, requiring adaptations to the terrestrial eye for proper light refraction; however, many cetaceans use vision above and below the surface, requiring eyes that work well in both environments. Finally, the diving behavior of cetaceans introduces rapidly changing light levels and additional physical stresses such as high ambient pressure (Kröger and Katzir 2008).

Cetacean eyes are positioned laterally but directed slightly anterior-ventrally. Visual fields are as wide as 130°. The eyes are mobile, although less so than in humans, and movements are

## Introduction

Cetaceans diverged from terrestrial mammals approximately 55 million years ago, and therefore, cetacean sensory systems have evolved from terrestrial mammalian systems, and many structures and functions are similar. However, the aquatic environment is radically different from the terrestrial environment in terms of signal production, transmission, and reception. Consequently, considerable adaptation and modification of the sensory systems has been observed in the cetaceans.

The two major taxonomic groups of cetaceans are the mysticetes (the baleen whales, such as the

relatively slow. All cetaceans (except the Ganges and Indus River dolphins, *Platanista gangetica gangetica*, *P. g. minor*, see below) have the standard mammalian oculomotor muscles but have an additional retractor muscle allowing axial movements (in-out) of the eye. The eyes and eyelids can move independently of each other, a feature that is easily observable when cetaceans sleep. The eyes of dolphins can move anteriorly by up to 15 mm, so that visual fields overlap by 20–30°. However, uncrossed optic fibers have not been found in dolphins, therefore true binocular vision based on the interaction of crossed and uncrossed optic fibers may not be present. Eyes in cetaceans are anteriorly flattened (as opposed to nearly spherical in terrestrial mammals) (Supin et al. 2001; Mass and Supin 2007).

In terrestrial mammal eyes, most light refraction (for focusing on the retina) is accomplished by the cornea, which separates air from the fluid-filled eye, although small adjustments of the lens also contribute. This mechanism depends on the large difference in refractive indices between air (refractive index  $\sim 1$ ) and the corneal tissue ( $>1.35$ ). However, seawater has a refractive index similar to the eye, severely reducing the refractive power of cornea. Cetaceans have adapted to this problem by developing large, nearly spherical lenses to focus light on the retina (similar eye morphologies are observed in other aquatic species, e.g., fish). The large curvature of a near-spherical lens increases refractive power and provides well-focused images on the retina (Mass and Supin 2007). This provides cetaceans with high levels of underwater visual acuity. For example, underwater visual acuity of the bottlenose dolphin, *Tursiops truncatus*, was measured at 8.2 arc minutes at 1 m (Madsen and Herman 1980).

Adaptations for underwater vision have obvious importance for cetaceans, however many cetaceans also use vision above the surface of the water and therefore must retain visual acuity in the aerial environment. Refraction at the cornea should result in cetaceans being severely myopic (nearsighted) in the aerial environment but this is prevented by several mechanisms. The cornea is characterized by flattened regions with little refractive power, centered in the nasal and

temporal regions of eye (approximately anteriorly and ventrally from the optical axis). Aerial myopia is also prevented by muscular movement of the eye to reduce intraocular pressure and by displacing the lens further into the eye. Finally, aerial myopia is prevented by drastic pupil restriction. In this way, the eye behaves like a pinhole camera, allowing dimmer images but with good focus over a wide depth of field (Supin et al. 2001; Mass and Supin 2007). Although the mechanisms for the reduction of aerial myopia are not fully understood, these features appear to provide high levels of aerial visual acuity (e.g., bottlenose dolphin aerial visual acuity 12.5 arc minutes at 2.5 m and longer, Madsen and Herman 1980).

The pupil must be able to accommodate a wide range of illumination levels due to diving (which in many species extends to hundreds or even thousands of meters). In most species, the upper part of the iris has an operculum that can occlude the pupil. In low light levels, the operculum is raised to produce a round pupil that maximizes light entry. With increasing illumination, the operculum extends downward, eventually reducing the pupil to a U-shaped slit. At high illumination levels, the operculum advances fully leaving only two small holes in the iris for light to pass through (Kröger and Katzir 2008). Like the flattened areas of the retina, these holes are centered in the nasal and temporal regions of eye. Some baleen whales have small opercula not capable of occluding the pupil to this extent, and the Amazon River dolphin (*Inia geoffrensis*) does not have opercula but instead has round pupils even when constricted (Mass and Supin 2007, 2009). Like eye and eyelid movements, pupil movements are independent between eyes (Mass and Supin 2009).

Cetaceans, like terrestrial mammals, have densely packed photoreceptors in the retina (e.g., 400,000 cells/mm<sup>2</sup> in bottlenose dolphins; Dral 1977). The cetacean retina has a large number of rod cells, achromatic photoreceptors sensitive to low light levels. However, there are few cone cells, photoreceptors sensitive to higher light levels that can give rise to color vision (about 1–2% of photoreceptors; Peichl et al. 2001). Most terrestrial mammals have two types of cone receptors (S-opsin and L-opsin) allowing

for dichromatic color vision, however only L-opsin cone receptors have been found in cetaceans. This arrangement is also observed in nocturnal, terrestrial mammals. Therefore, cetaceans lack dichromatic color vision, and color discrimination is relatively poor (Reuter and Peichl 2008; Fasick and Robinson 2016). Some color sensitivity is based on the comparative signals from rod cells and cone cells (best sensitivity 488 and 525 nm, respectively; Jacobs 1993). The maximum sensitivity of cetacean rod cells is shifted toward blue wavelengths, which maximizes visual sensory input while at depth. This blue-shifting of maximum sensitivity is more pronounced in deep diving species (Fasick and Robinson 2016).

Like terrestrial mammals, retinal ganglion cells are not homogeneously distributed. While terrestrial mammals have single areas within the retina of high ganglion density, most odontocetes and all mysticetes studied have two high density areas connected by a region of higher cell densities. Ganglion cell densities have been found to be as high as 800 cells/mm<sup>2</sup>. The spatial pattern of these areas overlaps that of the flattened areas of the cornea and the pupil openings: in the nasal and temporal regions of the eye. Therefore, images with minimal distortion are projected onto these high resolution areas of the retina. It is thought that in aerial vision, the temporal high-resolution area of the retina is primarily used, while for underwater vision, both high-resolution areas are important (Supin et al. 2001). Unlike other cetaceans investigated, the Amazon River dolphin has only one high-sensitivity area in the retina (Mass and Supin 1989). In comparison to the terrestrial mammals, cetaceans have unusually large ganglion cells and low ganglion cell density; however, there is no clear explanation for this arrangement (Mass and Supin 2007).

Cetaceans also have a blue reflective tapetum lucidum behind the retinal pigment epithelium. This reflective protein layer reflects blue light back into the eye, increasing sensitivity in low-light conditions. The tapetum lucidum in cetaceans covers a large proportion of the eye's

interior in comparison to terrestrial mammals (Mass and Supin 2007).

Retinal ganglion cells transmit impulses from the photoreceptors through the optic nerve (cranial nerve II). Consistent with the large size but low density of the cetacean retinal ganglion cells, the optic nerve has a large diameter but a low density of nerve fibers (e.g., about 25% that of primates). The total number of optic fibers is highly variable across the cetaceans but roughly scales with body size. The visual system is well represented in the superior colliculus (midbrain), the lateral geniculate body (thalamus), and the visual cortex in the occipital lobe (Mass and Supin 2009).

Bottlenose dolphins have demonstrated inter-modal transfer between visual and auditory sensory systems. Objects that are known visually can be recognized acoustically through echolocation and vice versa (Harley et al. 1996). While most cetaceans have retained vision as an important sensory modality, the Ganges and Indus River dolphins are functionally blind. These odontocetes lack a crystalline eye lens and have no oculomotor muscles. In the now-extinct Yangtze River dolphin (*Lipotes vexillifer*), the eyes were functional but reduced. This regression of visual ability was potentially due to their low-visibility habitats; however, other cetaceans that live in low-visibility habitats (e.g., the Amazon River dolphin) do not have decreased visual systems (Mass and Supin 2009).

## Hearing

While light does not propagate well in aquatic environments in comparison to terrestrial environments, sound propagates unusually well. Sound attenuation is very low, especially for lower frequency sounds. Sound also travels much faster than in air (approximately 1500 m/s for sea water, approximately 345 m/s for air). Finally, while the acoustic impedance (a measure of how the acoustic medium dynamically responds to sound pressure) of air is very different than

biological tissues, the acoustic impedance of water is quite similar. These features of sound in water have led to a high dependence on sound for various activities and to a highly modified auditory anatomy. This dependence on acoustics and anatomical modification is especially pronounced in the odontocetes, who use echolocation for foraging and navigation (Au and Hastings 2008). Unlike vision, hearing is highly specialized for underwater hearing, and adaptations for terrestrial hearing have largely been lost.

As a group, cetaceans are able to hear an extraordinary range of frequencies; however, there is considerable specialization between the odontocetes and the mysticetes. Odontocetes specialize in high-frequency hearing, and this group has demonstrated the ability to hear frequencies from 200 Hz to above 200 kHz (for comparison, good human hearing is 20 Hz–20 kHz). High-frequency hearing in this group supports the use of high-frequency echolocation (e.g., peak frequencies >120 kHz), which provides better spatial resolution than low frequencies. High-frequency hearing has also been found for Microchiropteran bats, the other group which has demonstrated highly developed, high-frequency echolocation abilities (Au and Hastings 2008). Comparatively, little is known about the hearing thresholds of mysticetes; however, as a group they are specialized for low-frequency hearing. Mysticetes generally produce very low frequency communication sounds (mainly below 5 kHz, down to 10 Hz) which have very low acoustic attenuation, and these animals likely communicate over hundreds or even thousands of kilometers. Largely based on their sound production, mysticetes are thought to be able to hear frequencies below 10 Hz up to 30 kHz. This is supported by studies on ear anatomy and behavioral responses to sounds (Au and Hastings 2008; Ketten 2000).

The acoustic impedance of mammalian tissue is very similar to that of water; therefore, the typical terrestrial mechanisms of sound channeling and impedance-matching of the outer ear (e.g., elaborate pinnae, patent horn-shaped external

auditory meatus) are not effective nor necessary. Consequently, external pinnae are absent in cetaceans, and vestigial auditory meatus are thin and occluded, and appear to have no role in sound transmission (Hemilä et al. 2010). The challenge for cetaceans is that the similar impedances cause sound waves to travel directly from the medium into the body, causing vibrations in bony structures such as the skull (bone conduction). Because of this, and the increased speed of sound in water, the directional cues used by terrestrial mammals are challenging (interaural time-of-arrival and intensity differences). Cetaceans avoid bone conduction by isolating their ears from the rest of the skull (see below). In addition, the large size of many cetaceans and the sensitivity to high-frequency (and therefore short wavelength) sounds results in good directional hearing in cetaceans (Au and Hastings 2008).

The route in which sounds reach the ears has been well studied in odontocetes, especially bottlenose dolphins. Odontocetes appear to have two frequency-dependent sound paths. Lower frequency sounds (e.g., whistles, used in many species for communication) appear to be transmitted through lateral pathways on the head (i.e., near the vestigial external auditory meatus) (Ketten 2000). In bottlenose dolphins, this pathway is most sensitive to frequencies between 16 and 22.5 kHz (Popov et al. 2008). Dolphins have also developed a novel method for the reception and transmission of high-frequency sounds to the ear. The lower mandible is very thin and filled with a fatty tissue which conducts acoustic vibrations very efficiently. This mandibular fat pad extends posteriorly to the middle ear, acting as a sound channel. The mandibular sound channel is most sensitive to high-frequency sound from the anterior direction, and therefore appears to have evolved for the reception of the return signals from echolocation (Au and Hastings 2008). In bottlenose dolphins, this sound channel is most sensitive to sounds between 32 and 128 kHz (Popov et al. 2008). In both cases, sounds are transmitted directly to the middle ear; the tympanum in odontocetes has little or no function in hearing but instead has a role in

pressure regulation (Numella 2009). The exact sound route in mysticetes is unclear. Fin whales appear to use bone conduction for low-frequency hearing, likely applicable to other mysticetes due to similarities in ear anatomy (Cranford and Krysl 2015).

Like all mammals, the middle and inner ears are surrounded in bony cavities (the auditory bullae), but cetacean auditory bullae are unusually dense. The tympanic and periotic bones of the auditory bullae have separated from the rest of the skull, and are known as the tympanic bullae or the tympano-periotic complex, and house the inner and middle ears. In odontocetes, the tympanic bullae are completely isolated from the rest of the skull by ligaments, mucosa, and air sacs. This isolation is thought to facilitate directional hearing and may prevent the transmission of self-produced sounds directly to the ears. In mysticetes, the isolation of the tympanic bullae is not complete, and large body size may be more important for directional hearing (Au and Hastings 2008; Ketten 2000).

In terrestrial mammals, the middle ear ossicles (the malleus, incus and stapes) connect the tympanic membrane to the oval window of the inner ear. Vibrations are transmitted along the ossicular chain in order to set the inner ear fluid in motion. In odontocete cetaceans, the ossicular chain does not connect to the tympanic membrane but instead connects to the tympanic plate (the thin lateral wall of the tympanic bone). The mandibular fat pat extends to the tympanic plate, and sounds from this route vibrate the tympanic plate and consequently the ossicular chain (Hemilä et al. 2010). The ossicular chain also contacts the thin lateral wall of the temporal wall of mysticetes; however, the term tympanic plate is a specific, functional term for the odontocete thinning of the tympanic bone, as it has a function in hearing. It is not known if the thinned part of the tympanic bone has a similar function in mysticetes (Numella 2008). Cetacean ossicles are enlarged and heavy in comparison to terrestrial mammals; however, this does not decrease frequency response as it would in terrestrial organisms as heavy ossicles are able to

transmit high frequencies in water (Numella 2009).

As in all mammals, the cetacean inner ear is known as the cochlea. The cochlea is a coiled structure filled with endolymph and perilymph. Vibrations at the oval window are transferred to the fluid within the cochlea, which cause displacement of the auditory sensory hair cells in a structure known as the organ of Corti. The organ of Corti is supported by the basilar membrane, both of which run the entire length of the coiled cochlea. As sound waves entering the cochlea cause the basilar membrane to vibrate and deform, the physical properties of the basilar membrane determine the frequencies to which the ear is sensitive. In odontocetes, the basilar membrane is very stiff, allowing them to perceive and process very high frequencies, while in mysticetes, the basilar membrane is relatively flexible and more suitable for detecting low frequencies. While odontocetes have about the same number of cochlear hair cells as many other mammals, they have  $2\text{--}3\times$  as many associated ganglion cells, which is certainly a key component in their exceptional hearing abilities (Au and Hastings 2008; Ketten 2000).

Bending of the hair cells in the organ of Corti leads to nerve impulses in the cochlear nerve (part of the vestibulocochlear nerve, cranial nerve VIII). Acoustic nerve impulses travel to the inferior colliculus (midbrain), lateral geniculate body (thalamus), and to the auditory cortex. In odontocetes, the auditory cortex has been found in the suprasylvian gyrus, located along the vertex of the hemispheres, and in the temporal lobe (Ridgway 2000; Hof et al. 2005). As in all mammals, tonotopic organization is observed from the inner ear to the auditory cortex (e.g., in the basilar membrane, the base is most sensitive to high frequencies and the apex to low frequencies, and this frequency organization is conserved throughout the acoustic nervous system) (Au and Hastings 2008).

The importance of the auditory system can be observed in the degree of neural investment. For example, the ratio of nerve fibers in auditory nerve in comparison with optic nerve is up to three times

greater in cetaceans than in terrestrial mammals. In odontocetes, which make more use of acoustic information due to their dependence on echolocation, the inferior colliculus and medial geniculate body are far larger than their visual counterparts (the superior colliculus and the lateral geniculate body). Odontocetes in particular have developed very rapid auditory temporal processing, high sensitivity, and frequency discrimination (Au and Hastings 2008).

## Chemoreception

In cetaceans, chemoreception can occur through taste and smell; however, chemoreception abilities are reduced in the cetaceans in comparison to terrestrial mammals. The vomeronasal organ (organ of Jacobson) is absent in modern cetaceans, although evidence for a vomeronasal organ has been found in a neonate gray whale (*Eschrichtius robustus*; Kienle et al. 2015). It has been suggested that chemoreception, at least in odontocetes, is a combined sense involving aspects of both taste and smell (Kuznetsov 1990).

Taste (or gustation) is the ability to detect waterborne compounds. Cetaceans generally have simple tongues with few or no taste buds (the sense organs of taste), although some studies have found taste bud like organs contained in pits found in dolphin tongues. Despite this, bottlenose dolphins have been shown to detect a variety of tastes, including the four tastes that humans perceive (sour, bitter, salty, and sweet) at level similar to humans. Nervous pathways are not well understood but may involve cranial nerves V, VII, IX, and/or X. Taste is thought to be perceived in the parietal lobe of the brain (Kremers et al. 2016).

Smell (or olfaction) is often defined as the ability to detect airborne volatile compounds, although waterborne olfaction is present in fish (Hemilä and Reuter 2008). In olfaction, molecules dissolve in the mucous of the olfactory epithelium. This activates olfactory receptors on the cilia of sensory neurons, transmitting impulses through cranial nerve I, which leads to the olfactory bulb in the frontal lobe for processing

(Kremers et al. 2016). As cetaceans close their nasal apertures underwater, any olfactory senses are likely limited to the aerial environment.

Odontocetes lack olfactory bulbs and cranial nerve I and are generally thought to have no olfactory capabilities (Pihlström 2008). However, innervated chemoreceptor cells have been found in the nasal cavities of harbor porpoises (*Phocoena phocoena*), therefore some level of olfaction may be present (Berhmann 1989). Olfactory bulbs have been reported in several mysticetes and have been well documented in bowhead whales (*Balaena mysticetus*). Olfactory epithelium has also been found in bowhead whales, and this species appears to react to airborne smells. It is thought that any sense of olfaction may be useful in locating the presence of planktonic prey by airborne smell (Thewissen et al. 2011).

## Somatosensation

Somatosensory systems include the sense of touch, pain, temperature and body position, and involves several receptors including mechanoreceptors (for touch) and nociceptors (for pain). While other sensory systems have receptors concentrated in the head, this is not the case for somatosensation. For example, mechanoreceptors are spread over much of the surface of the body. Cetacean skin is well innervated and is very sensitive to touch. Dolphins are most sensitive in their anterior region (the rostrum, eyes, melon, and near the blowhole), corresponding to high numbers of cutaneous mechanoreceptors. High sensitivity near the blowhole is likely important for determining when the blowhole is above the surface before breathing (Kremers et al. 2016; Thewissen 2009). Tactile contact also appears to be an important form of communication in several species (e.g., *Atlantic spotted dolphins*, *Stenella frontalis*; Dudzinski 1998). Because of the high density of water, cetaceans can detect mechanical disturbances in the environment at comparatively large distances. Some species have facial vibrissae (e.g., the Amazon River dolphin, mysticete cetaceans), and it is thought that deflection of these

hairs provides additional tactile information (Dehnhardt and Mauck 2008). Somatosensory information is processed in the posterocruciate gyrus of the cerebral cortex (Supin et al. 2001).

## Balance

Like all mammals, cetacean's sense of balance, or the perception of movement and spatial orientation, is achieved through the vestibular system located in the inner ear. The vestibular system consists of two independent motion sensors. First, two well-developed otolith organs are located in the utricle and saccule. These are responsive to linear acceleration (e.g., changes in gravitational direction). Changes in inertia displace the position of the otoliths, which are detected by sensory hair cells. Although this system is well developed in cetaceans, relatively little is known about the cetacean otolith organs (Spoor and Thewissen 2008). The second type of motion sensor is the semicircular canal system, which perceives angular movements. The three semicircular canals (anterior, posterior, and lateral) are embedded within a bony matrix. Each canal contains a semicircular duct which is connected with the utricle, forming an endolymph filled circuit. At one end of each semicircular duct, a dilation (the ampulla) containing a gelatinous structure (the cupula) seals the canal. Acceleration and deceleration cause the endolymph to lag behind due to inertia, and such lags are detected by hair cells in the cupula. As the three semicircular ducts of each ear are approximately orthogonal, any rotation can be sensed by at least one canal (Spoor and Thewissen 2008; Spoor 2009).

In general, more agile and maneuverable mammals have larger-arc'd semicircular canals. Although many cetaceans are highly agile and maneuverable (e.g., spinner dolphins, *Stenella longirostris*), cetaceans have relatively small semicircular canals (arc and lumen size) in relation to body size. For example, the semicircular canals of blue whales are slightly smaller than those of humans. This is thought to be because

cetaceans are generally quite buoyant and therefore, do not experience significant gravitational forces, nor are they normally in contact with the substrate. In addition, cetaceans have reduced mobility of the head in relation to the body (e.g., some species have fused cervical vertebrae). This could potentially lead to stronger rotary input (from the entire body) and overstimulation of the vestibular system. Therefore, reduced semicircular canals may be an adaptation to avoid overstimulation of the vestibular system, especially during acrobatic movements. Another notable difference between cetacean semicircular canals is that the lateral canal is the largest while the posterior canal is the smallest, while in other mammals the lateral canal is the smallest (Spoor and Thewissen 2008; Spoor 2009).

Nervous impulses from the vestibular system likely reach the central nervous system through the vestibulocochlear nerve (cranial nerve VIII). Information is processed in the vestibular brain stem nuclei and motor nuclei to facilitate movements to stabilize the body (Sipla and Spoor 2008).

## Electroreception

Electroreception is common in aquatic vertebrates but is rare in mammals. The Guiana dolphin (*Sotalia guianensis*) has well innervated, enlarged hair follicles on the lower jaw which have been shown to be sensitive to weak electrical fields. It is thought that this sense may be used to find fish buried in the sediment. Although electrosense has not been found in other cetacean species, mandibular hair follicles are found in other cetaceans. The benthic foraging behavior of other cetacean species suggests that electrosense may be more widespread in the cetaceans (Wilkins and Hofmann 2008; Czech-Damal et al. 2012).

## Magnetoreception

Magnetoreception, the ability to perceive magnetic fields, has been suggested for cetaceans,

but virtually nothing is known about if they possess this sense or how it is used. Magnetoreception was first suggested for cetaceans based on field observations of strandings, as the locations of strandings were found to be correlated to geomagnetic minima. It has also been suggested that baleen whales could use geomagnetic sense for long-distance migration, as fin whale migration routes in the western Atlantic were correlated with low geomagnetic intensity. Magnetite has been found in the brains of humpback whales, bottlenose dolphins, and short-beaked common dolphins (*Delphinus delphis*). Associated nerve fibers were also found in the short-beaked common dolphin. Few controlled studies have been carried out on cetacean's ability to detect magnetic fields, and results have been contradictory; far more research in this area is required before this sensory system is confirmed in cetaceans, let alone understood (Hofmann and Wilkens 2008).

## Conclusion

Cetacean sensory systems and abilities have undergone tremendous adaptation from their terrestrial ancestry in a relatively short time. All cetaceans appear to have a great dependence on acoustics, especially the odontocetes who use echolocation for foraging and navigation. Vision has been retained as an important sensory modality despite the limitations of vision underwater and the challenges of having eyes that function in both the aquatic and aerial environments. Somatosensation also appears to be an important and well-developed sense for cetaceans, while chemoreception and balance reception have been reduced. Cetaceans also appear to have some ability to detect electrical and magnetic fields. Several areas need more research, especially the sensory systems of mysticetes and nondelphinid odontocetes (e.g., beaked whales), as well as research into the less well-studied senses (e.g., electroreception).

## Change Blindness

Walter T. Herbranson  
Whitman College, Walla Walla, WA, USA

### Definition

Change blindness is a phenomenon of visual attention in which changes to a visual scene may go unnoticed under certain circumstances, despite being clearly visible and possibly even in an attended location. For example, the appearance of an object might not be noticed if it coincides with a disruption of visual continuity such as a flicker or an eye movement. Change blindness is an example of a striking limitation to visual attention and indicates that visual representations are more sparsely detailed than would sometimes be assumed. The phenomenon can occur under a wide array of circumstances, as well as in multiple sensory modalities, and has been demonstrated in some nonhuman animals.

### Introduction

The first experimental investigations of change blindness were of saccade-contingent changes: changes that occur at the same time as eye movements. McConkie and Currie (1996), for example, had human participants view photographic displays on a computer screen while monitoring their eye movements with eye trackers. During

viewing, sudden changes were made to the display and participants were asked to search for them. For example, an object in the scene might change color, change location, or disappear entirely. Changes that happened during an eye saccade were more difficult to detect than those occurring during a fixation. Even prominent changes encompassing a large portion of the screen frequently went unnoticed if they happened while the viewer's eyes were in motion.

Subsequent research using different methods showed that this kind of failure to detect changes is not limited to eye movements; change blindness can occur under a wide variety of conditions and at any time. For example, in the flicker task, one of the most commonly used methods of investigating change blindness, participants search for a difference between two sequentially alternating visual scenes that are identical save for a single feature (Rensink et al. 1997). If the scenes alternate instantaneously, with one image or the other always visible, the change is usually seen quickly and effortlessly. Participants often report that the change “pops out” at them. On the other hand, if a short inter-stimulus interval (ISI) is inserted between each image, during which the screen is blank, the change is much more difficult to identify and requires an active, location-to-location search. Consequently, accuracy is worse, and latency to identify the change is longer. The flicker task is particularly appealing to experimental psychologists because it allows them to easily isolate and manipulate specific aspects of a change, such as its size, location, or salience. The method also establishes the practical importance of change blindness, by showing that change blindness can occur at virtually any time, regardless of what the participant is doing or where she is looking. The earlier demonstrations of saccade-contingent change blindness constrained it to the short moments of time when the eyes are in motion.

While the flicker task has been the most widely used procedure for studying change blindness, other methods have emerged that show the same pattern of results and illustrate that change blindness can occur under widely varying conditions. For example, one method is similar to the flicker

task, in that participants attempt to identify changes in alternating images. However, instead of including an ISI to induce a global visual disruption, a set of small local disturbances (“mudsplashes”) are superimposed onto the image at the moment of change (O’Regan et al. 1999). These mudsplashes are located so as not to obscure the change, but their presence nevertheless makes it more difficult for participants to identify the difference between images. Thus, the procedure illustrates that a global visual disruption (as in the flicker task) is not necessary for change blindness to occur. Yet another method uses gradual changes to produce change blindness. In this method, two images are prepared that are identical save for one feature (such as the presence, location, or color of an object). One image is presented initially, but gradually dissolves into the other over the course of several seconds, and participants are asked to search for and identify the change (Simons et al. 2000). In this case, there is no visual disruption at all, and yet participants often fail to notice the change, especially if the rate of change is slow.

Not only can change blindness be produced by a widely varying collection of laboratory procedures, there appear to be parallels in other sensory modalities. Using parallel methods, researchers have shown that people can be made to fail to detect changes in auditory (Gregg and Samuel 2008), tactile (Gallace et al. 2007), and olfactory (Sela and Sobel 2010) stimuli. While less research has been done on these nonvisual equivalents of change blindness, their existence would seem to suggest that change blindness could be due to a general nonmodality specific feature of attention.

Research programs on change blindness carry some important implications for cognitive science and our understanding of how we experience the world around us. While our momentary experiences during visual fixation may be quite detailed, very little of that detail is maintained from one view to the next. Instead, the visual memory that persists from moment to moment is quite sparse, consisting of little more than the meaning or gist of a scene (Simons and Levin 1997). Thus, we fail to notice many feature-level changes because the representations of those initial features are

transitory and do not persist across the change. Nevertheless, the details that are preserved appear to be sufficient to allow people to interact with a complex world quite successfully, at least under most everyday circumstances.

## Change Blindness in Nonhuman Animals

If change blindness is in fact a wide-ranging general consequence of sparsely detailed representations of visual scenes, we might expect to see the same phenomenon in some nonhuman animals that have similar visual systems. Indeed recent research has shown predictable change detection failures in nonhuman animals using methods patterned after those originally developed to investigate change blindness in humans.

Primates, of course, are closely related to humans and have visual abilities that are comparable in many ways. Thus, they make a logical population for initial comparative research into change blindness. Tomonaga and Imura (2015) used a variant of the flicker paradigm to study change blindness in chimpanzees and humans. They presented alternating displays consisting of several line drawings on a CRT monitor in a task inspired by the flicker paradigm. On each trial, one of those line drawings changed between alternating displays by either shifting position, changing shape, or appearing/disappearing, and chimpanzees were trained to touch the location of the line drawing that changed. As in other implementations of the flicker task, some trials included a blank field that appeared at the time of a change, producing a global disruption of visual continuity. Inclusion of those blank fields led chimpanzees (like humans) to make more errors and to respond more slowly to all three kinds of changes, indicating that change detection was more difficult.

Cavanaugh and Wurtz (2002) used a similar approach to study change blindness for motion change in macaques. Their monkeys viewed several fields of moving dots on a display, one of which could change its direction of movement. Monkeys were then rewarded for making an eye movement in the direction of the field that had

changed its direction of movement (or for not making an eye movement if no change had occurred). As with other change blindness tasks, they included a global visual disruption on some trials by presenting a brief blank field at the onset of the change. Change detection accuracy was impaired on those trials that featured a blank field, a standard change blindness effect. Accuracy on blank field trials improved if the location of the change was cued ahead of time, indicating that monkeys were still capable of detecting those changes, and indeed could strategically use information to attenuate the effects of change blindness.

Pigeons are more distantly related to humans, but have excellent visual acuity and have long been used to study visual attention in comparative psychology. Herbranson et al. (2014) used a version of the flicker paradigm to study pigeons' ability to detect changes in a visual display. Birds viewed alternating collections of features (up to eight lines of varying orientations) projected onto three response keys in an operant chamber. One of the line features present on one response key appeared and vanished across presentations, and after observing a required number of iterations, pecks to the location of the change were reinforced. Some trials contained an ISI between successive displays (causing a global visual disruption) and other trials did not. Pigeons were less likely to peck the location of the change if an ISI was present, the same change blindness pattern seen in the flicker task with human participants. Accuracy remained better than chance however, showing that pigeons were still capable of correctly identifying changes on some ISI trials. Subsequent research in the same lab (Herbranson and Jeffers 2017) used the same methodology to demonstrate change blindness for color changes, a potentially more subtle variety of change. Again, pigeons were less likely to detect a change if an ISI was present. Furthermore, change blindness in pigeons appears to be affected by some of the same factors that affect change blindness in humans and in the same way. Specifically, the magnitude of impairment caused by visual disruption depends on both the duration of an ISI and the salience of the change (Herbranson 2015; Herbranson and Davis 2016).

Whereas the flicker task produces change blindness via a global visual disruption, recall that such a disruption is not necessary in humans, who also show change blindness for gradual changes that involve no visual disruption at all. Hagmann and Cook (2013) showed that this is also the case for pigeons. They trained birds to detect continuous, gradual changes in brightness on a computer display using a go/no-go procedure. Pigeons viewed a colored rectangle that was either constant or continuously changing in brightness. Pecks on constant-brightness trials were reinforced on a VI schedule, and pecks on changing-brightness trials resulted in a timeout. Birds suppressed pecking on changing trials, but took longer to do so when the rate of change was slower. Thus, more gradual changes were more difficult to detect, as they are for humans. Again this shows that changes may go unnoticed, even when there is no disruption of visual continuity to obscure the change. In the context of the previously described comparative research, it also shows that change blindness in pigeons is not tied to one specific laboratory procedure such as the flicker task.

## Conclusion

Change blindness has been a topic of considerable interest in cognitive psychology in recent decades. Research on humans indicates that it can occur in a wide variety of situations, and consequently can be studied using many different procedures. The resulting collection of research tools includes several tasks such as the flicker paradigm that can be readily adapted to study change blindness in non-human animals. While only a small number of species have been tested and only a subset of the developed change blindness tasks have been adapted, the available results show striking parallels with the results produced by humans.

Change blindness research has thrived in part because it presents results that do not match most people's subjective perceptions. Our momentary visual experience appears detailed, even though that detail is transitory and does not persist across views, and most people overestimate their ability to detect changes ("change blindness blindness";

Levin et al. 2000). The existence of change blindness in nonhuman animals might initially seem just as puzzling, given that vigilance and the ability to quickly and accurately detect changes would intuitively seem to have survival value for many animals. Simons and Levin (1997) propose that the sparsely detailed visual representations that give rise to change blindness may serve to provide stability and continuity from moment to moment. Thus, one can have a detailed perceptual experience at any instant, but by preserving only those components that are likely to be important, the relevant features in the next glance can be quickly matched up without the overwhelming task of tracking and linking each and every minute detail. Presumably this logic would apply as well to nonhuman animals, who often have to solve the same perceptual problems as humans, with even more limited neural resources.

of Texas Health Science Center at Houston,  
Houston, TX, USA

Understanding memory is one of the great scientific challenges of the twenty-first century. An essential component of all memory is the ability to store and process information in working

memory (WM, sometimes called short-term memory, See also chapters “► [Working Memory](#)” and “► [Short-term Memory](#)”). Over the past 29 years, the working-memory task of choice has been *change detection* where (mostly) humans have been presented with an array of visual stimuli and following a short delay they report which stimulus changed, or whether there was a change (e.g., Alvarez and Cavanagh 2004; Cowan 2001, 2005; Eng et al. 2005; Luck and Vogel 1997; Pashler 1988; Rensink 2002). Conclusions from human change-detection memory research has suggested that human visual working memory (VWM) is limited in capacity to about  $4 \pm 1$  items (e.g., Cowan 2001, 2005). In one version of change detection, several objects (e.g., colored squares or clip art) are presented as a sample array, to be remembered. Following a retention delay, a test array is presented with one object changed; the test array can include all unchanged sample-array objects or a smaller number, for example one changed object and one unchanged object in a 2-alternative forced-choice test. Subjects typically identify the changed object, for example by touching the changed object. Change detection is well suited to investigating working memory because many memory objects can be presented simultaneously within the encoding time period of VWM. Furthermore, change detection has been shown to utilize visual memory, independent of verbal rehearsal, making it a suitable task for testing VWM of nonhuman animals with well-developed visual systems (Alvarez and Cavanagh 2004; Luck and Vogel 1997). It is important to understand how VWM works in nonhuman species to understand VWM generally, including evolutionary continuity of this important early memory processing stage. But difficulties in obtaining the necessary high performance (see also chapter “► [Evolution](#)”) accuracies have stymied attempts to obtain viable animal VWM results from change-detection tasks until recently (Buschman et al. 2011; Devkar et al. 2015; Elmore et al. 2011, 2012; Elmore and Wright 2015; Gibson et al. 2011; Heyselaar et al. 2011; Lara and Wallis 2012; Lazareva and Wasserman 2016; Wright et al. 2010; Wright and Elmore 2016).

## Comparing Monkey and Human Change Detection

Rhesus monkeys are an ideal species to compare to humans because they perform well in other visual memory tasks (e.g., list memory) and because they are the standard medical model for humans. Much of what we learn about VWM in rhesus monkeys should be applicable to understanding human VWM. A memory model with rhesus monkeys can provide the foundation for types of memory studies that are difficult or impossible to conduct with humans, such as lesions, electro physiological recordings, pharmacological and gene expression manipulations.

One such recent investigation compared two rhesus monkeys and six human subjects tested in nearly identical change-detection tasks (Elmore and Wright 2015). The basic task is illustrated in Fig. 1a. Two important parameters were manipulated in order to investigate the functional relationships of VWM: display size and stimulus type. Display size refers to the number of items presented in the sample array. Monkeys were tested with display sizes of 2, 4, and 6 and humans were tested with display sizes of 2, 4, 6, 8, and 10. Both species were tested with two types of stimuli, clip-art and colors (Fig. 1a). Monkey and human performance was high and above chance (50%) at all display sizes and decreased as display size increased (Fig. 1b).

Comparing monkeys and humans in terms of VWM capacities, the monkeys showed capacities equal to (clip art) or less than one item (colored squares), a result that makes little or no sense for a species' survival. Therefore, a continuous-resource, detection-theory account of VWM was used to compare these species VWM (Fig. 1c). Unlike fixed-capacity accounts (e.g.,  $4 \pm 1$  items), the continuous-resource account predicts that working memory limitations stem from noise in the internal representation of each item. As display size increases, an item will receive less resource on average and consequently has a noisier internal representation (e.g., Wilken and Ma 2004; Bays and Husain 2008). Determining which stimulus has changed in a change detection task becomes

**Change Detection, Fig. 1** (a) Progression of events for two clip-art trials in the change-detection task. (b) Percent correct for humans and monkeys tested with clip art and with *colored squares*. (c) Calculations of  $d'$  values for each stimulus type and display size, where a *hit* ( $H$ ) was a correct response to the lower numbered location in the test display. A *false alarm* ( $FA$ ) was defined as a response to the lower

numbered location when that location did not contain the changed item. And  $d'$  varied according to  $d' = \frac{[z(H) - z(FA)]}{\sqrt{2}}$ . (d)  $d'$  values were fit by power-law functions because memory sensitivity ( $d'$ ) should be proportional to  $1/N$ , where  $N$  is the number of items in the display,  $Y$  is a constant, and  $x$  is the exponent:  $d' = Y \cdot N^{-x}$

more difficult as display size increases, not because the capacity has been exceeded, but rather because it becomes a problem of extracting a signal (memory for the stimuli) from a noisy representation. Differences between humans and monkeys can be explained by differences in level of overall attention to the task, as attention has the effect of increasing the signal-to-noise ratio. In the continuous-resource model, attention can vary over a wide range of attention levels, unlike the fixed-capacity account. Further, as attentional variability contributes to noise levels, it is already accounted for by the continuous-resource account. The continuous-resource account employs  $d'$  values from signal detection theory as a measure of memory sensitivity (Wilken and Ma 2004; Green and Swets 1966; Macmillan and Creelman

2005; Elmore et al. 2011). Moreover,  $d'$  decreases as display size increases and are well fit, as they should be, by a power law function in Fig. 1d.

As with capacity estimates,  $d'$  was found to be greater for human subjects than for monkeys. Monkey  $d'$  values were well fit by power law functions; the  $R^2$  values were 0.98 for color stimuli and 0.99 for clip art. Human  $d'$  values from both the color and clip art condition were also well fit by power law functions;  $R^2$  was 0.75 for colors and 0.70 for clip art. The continuous-resource account of monkey and human VWM memory fits into 50 years of development of signal detection theory. Signal detection theory is the dominant framework to account for how humans and animals perceive stimuli in noise (Green and Swets 1966; Macmillan and Creelman 2005).

Functional relationships showing how performance ( $d'$ ) changes with memory load (sample display size) according to the continuous-resource model go beyond functional relationships of percent correct changes with sample display size (e.g., Fig. 1b). The latter is a descriptive account without accounting for *how* memory varies with display size or *how* the brain might produce these memory results. The continuous-resource account postulates that  $d'$  changes should vary inversely as a power function of display size. The fixed-capacity model, on the other hand, predicts that capacity will be the same at all display sizes, except for display sizes less than the capacity limit where performance should be perfect (100% correct). Perhaps most discriminating for these VWM accounts and models is how memory might operate at the neural level. The fixed-capacity model says that each item is stored and remembered perfectly – or not at all. When all the memory slots are filled, then nothing is remembered about any additional item for that VWM bout. This is problematic from a neurobiological point of view. The storage, maintenance, and retrieval of information (i.e., memory) are all likely probabilistic. In a broader sense, the nervous system is inherently noisy and its computations are probabilistic (e.g., Bays and Husain 2008; Ma and Jazayeri 2014). The continuous-resource model captures the noisy nature of the nervous system – and hence provides a plausible account of how the VWM system might work, in general.

## Comparing Pigeon, Monkey and Human Change Detection

Another recent comparative change-detection study was conducted with pigeons using the same basic change-detection procedure (2-stimulus test) for direct comparisons to the results from monkeys and humans that were shown in Fig. 1 with colored-square stimuli (Wright and Elmore 2016). The top of Fig. 2 shows the task progression with colored-square stimuli and below are graphs of percentage correct, computed capacities, and  $d'$  power-law functions for pigeons, monkeys, and humans. Percent correct performance

declined as a function of display size with humans outperforming pigeons and monkeys by 15.4% and 27.3%, respectively. VWM capacity was calculated from:  $A = \left[\frac{N-C}{N}\right]^2 \times 50\% + \left\{1 - \left[\frac{N-C}{N}\right]^2\right\} \times 100\%$ , with  $A$  being the empirical accuracy,  $N$  the display size, and  $C$  the VWM capacity (Eng et al. 2005). The mean capacities with colored squares were 0.77, 0.71, and 2.46 for pigeons, monkeys, and humans, respectively. While human capacity estimates are greater than two items, the animals had capacity limits less than a single item according to the fixed capacity account. Such capacity limits make little or no sense; how could pigeons and monkeys survive (predators, food sources, mates, etc.) with working memory capacity limits substantially less than one item?

By contrast to fixed-capacity limits, pigeon, monkey, and human performances were well characterized by the continuous-resource model with  $d'$  power-law exponents that characterize the rapidity of change in  $d'$  over the range of set sizes tested. Comparing exponents across species revealed small but orderly differences:  $-1.03$ ,  $-0.94$ , and  $-0.86$  for pigeons, monkeys, and humans, respectively. Multiplicative coefficients of the power law characterize “level” of the function, the Y-axis intercept, extrapolated memory for a single item, and overall memory sensitivity ( $d'$ ). Not surprisingly, humans far surpassed the animals in this measure. But interestingly, pigeons showed a marginally superior coefficient compared to monkeys (3.18, 2.27, and 6.34) for pigeons, monkeys, and humans, respectively with a significant difference in coefficient among species.

## Mechanisms of Working Memory by Manipulating Change

Studies aimed at understanding the neural correlates of VWM content limitations have so far been guided by fixed-capacity models (Buschman et al. 2011; Vogel and Machizawa 2004). According to these accounts, only a fixed number of items (referred to as the capacity) are held in memory with high quality and no information is retained

**Change Detection, Fig. 2** *Top*: progression of events for two trials with colored squares in the change-detection task. *Bottom left*: pigeon percent correct performance, capacity, and power-law fits for  $d'$  values. *Bottom middle*: monkey percent correct performance, capacity, and power-law fits for  $d'$  values. *Bottom right*: human percent correct performance, capacity, and power-law fits for  $d'$  values

about any other items (e.g., Pashler 1988; Cowan 2001, 2005; Luck and Vogel 1997). More recently, alternative proposals have gained scientific following where “memory resource” is distributed across all items seen and memory precision is inversely related to the number of

objects in the visual scene (Wilken and Ma 2004; Bays and Husain 2008; Van den Berg et al. 2012; Keshvari et al. 2013). To test among fixed-capacity and multiple types of distributed resource models, monkeys and humans were tested with the same change-detection procedures

where multiple items (line tilts) were presented with different magnitudes of change at test (Devkar et al. 2015; also see Keshvari et al. 2013). Three monkeys and 10 humans viewed sample arrays of 2, 3, 4, or 5 randomly oriented lines/bars (in 6 possible locations); following a delay subjects were presented with two (randomly chosen) items from the sample array with one item changed ( $10\text{--}90^\circ$  in  $10^\circ$  steps) in orientation (Fig. 3). Correct responses of touches to the changed item were reinforced with Tang orange drink or banana pellet (monkeys) and green light and tone (humans). Trials were separated by 3 s. Monkeys and humans each were tested on 11,520 total trials and 1152 trials, respectively and their mean results are shown in Fig. 4.

Results from monkeys and humans were evaluated according to four of the leading models of VWM: Fixed Capacity, Equal Precision, Fixed Capacity plus Equal Precision (identified as, Fixed Cap + Resource), and Variable Precision (Fig. 5). According to the Fixed Capacity account, a fixed number of items (the capacity) are kept in memory with infinite precision, while remaining items are absent from memory (e.g., Pashler 1988; Cowan 2001; Luck and Vogel 1997). According to Equal Precision, all items are remembered with

equal memory precision which decreases with increasing set size. Fixed Capacity plus Equal Precision (Fixed Cap + Resource) combines elements of Fixed Capacity and Equal Precision where only a fixed number of items share limited memory resource (e.g., Zhang and Luck 2008). Variable Precision is where memory resource is distribution across all items but in variable amounts and can vary from item to item and trial to trial (e.g., Van den Berg et al. 2012; Keshvari et al. 2013).

Evaluations were determined by maximizing (i.e., bootstrapping) the likelihood estimation of parameters from each model, and the model fits are shown in Fig. 6 (see Devkar et al. 2015). The data from both species were well accounted for by a noise-based model in which memory precision is variable across items and trials (Variable Precision) as shown by 94% and 80% of variance ( $R^2$ ) accounted for, compared to 83% and 59% for Equal Precision and 32% and 23% for Fixed Capacity for monkeys and humans, respectively. These findings are consistent with previous findings with humans (e.g., Keshvari et al. 2013; Van den Berg et al. 2012). Moreover, combining Equal Precision with Fixed Capacity helped (86% and 71%, respectively) but did not fully salvage

**Change Detection, Fig. 3** Progression of events for a trial that begins with a touch to a centered *red dot*, followed by a sample array containing five line-tilt stimuli presented

for either 300 ms (humans) or 600 ms (monkeys), a delay of 1 s, and a test of two sample-array stimuli with one changed in orientation

**Change Detection, Fig. 4** Mean psychometric functions of for monkeys and humans with set sizes of 2, 3, 4, or 5 line-tilt items

the Fixed Capacity account as hoped (e.g., Anderson et al. 2011; Zhang and Luck 2008). Indeed, Bayesian Likelihood Factor analyses showed that the Variable Precision account was 178 million times more likely than the next best account, Fixed Capacity plus Equal Precision (see also chapter “► Model Fitting”).

Such clear conclusions about Variable Precision being the fundamental underlying process of monkey VWM as well as humans, establishes rhesus monkeys as model system of human VWM for exploring how VWM works in these species, including the neural networks that support VWM.

**Decision Mechanisms in Change Detection**

The previous section on VWM mechanisms discussed how variations in encoding precision of sample display items influences VWM. Precision also influences decisions in the observer’s decision-making stage that are separate from item encoding precision (see also chapter “► Decision-Making”). The change-detection task taps into both of these stages of VWM processing: The observer encodes and maintains information about the sample stimuli, compares its memory of the sample stimuli with the test stimuli at the corresponding locations, and then makes a decision about which test stimulus has changed leading to a response (Fig. 7b). In change-detection tasks, the inherent precision of one or more task-relevant stimuli can be manipulated by changing the reliability of the stimulus. In the example presented in this section, two different ellipse stimuli (different length/width ratios) were used to change precision in detecting orientation changes (Devkar et al. in press). The low-reliability ellipse was shorter and wider (fatter) making the orientation change more difficult to discriminate than the alternative high-reliability ellipse that was longer and narrower (see Fig. 7a). These combinations of reliable and unreliable stimuli were used to influence how monkeys and humans made decisions about which stimulus changed in orientation. Humans have been shown to make optimal decisions in VWM-based

**Change Detection, Fig. 5** Schematics of four VWM theories for presentations of two or five items to be remembered in accordance with how “memory slots” are filled with memory resource

## Monkeys

## Humans

**Change Detection, Fig. 6** Model fits for human and monkey performance shown in Fig. 4 according to the four VWM theories shown in Fig. 5

comparison tasks (Devkar et al. 2015; Keshvari et al. 2013; Van den Berg et al. 2012) and therefore might give more weight to the more reliable stimulus (longer and thinner ellipses) than the less reliable stimulus (shorter, wider ellipses). Based on the computed relative weight of evidence, the observer tends to choose the location with the higher probability of change (Ma 2012). Although monkeys and humans were shown in the previous section to have similar VWM encoding mechanisms (Variable Precision), the issue here is whether monkeys would employ similar (or different) decision processes in such a change detection task as do humans.

Two rhesus monkeys and ten humans were tested to determine similarities or differences in decision processes in nearly identical change detection tasks (Devkar et al. *in press*). Subjects were briefly presented with sample arrays containing three randomly oriented ellipses with reliability types (high and low reliability) also being

randomly selected, and were randomly located in 3 out of 6 positions on an imaginary circle (Fig. 7a). Following a delay, a test array was presented containing two randomly selected ellipses from the sample array, with one of the chosen ellipses undergoing a random orientation change (10–90° in 10° steps). As in the previous section, the correct response was to touch to the item with a changed orientation followed by reinforcement (monkeys) or feedback (humans).

Tests consisted of four possible conditions. Two conditions contained the same reliability stimuli, either both of high reliability or both of low reliability. The other two conditions were mixtures of both reliability stimuli, but in one condition, the change occurred in the high reliability stimulus and in the other condition, the change occurred in the low reliability stimulus. Of particular interest is how these subjects dealt with these stimuli in making their decision about which test stimulus changed.

**Change Detection, Fig. 7** (a) Trial example used to test monkeys and humans beginning with a *red* fixation dot, followed by a sample array containing three elliptical stimuli (two types) in any one of nine angular orientations. After a 1 s delay, two of the sample-array stimuli were tested with one changed in orientation. The correct response was a touch to the stimulus that changed in orientation. (b) Processing scheme leading to the decision

about which stimulus changed. (c) Psychometric functions for a mean of ten humans and two individual monkeys presented with either two high-resolution (HR) ellipses (*blue*), two low-resolution (LR) ellipses (*aqua*), or mixtures of HR and LR ellipses with orientation changes in the LR ellipse (*red*) or orientation changes in the HR ellipse (*green*)

The psychometric function results are shown in Fig. 1c. Humans and monkeys both showed the highest proportion correct in the condition where both test ellipses were of high reliability. They also showed the lowest proportion correct in the condition where both test ellipses were of low reliability. In the mixture condition, when the change was in the high-reliability stimulus, not surprisingly accuracy was higher than when the change was in the low-reliability stimulus, reflecting training to spot changes in orientation. Nevertheless,

when the change was to the low-reliability stimulus in the mixture condition, performance was better than when both test stimuli were of low reliability. Such results have important implications for decision-making strategies by monkeys as well as humans.

These findings converge on the conclusion that when confronted with choosing between a changed low-reliability stimulus and an unchanged high-reliability stimulus, monkeys and humans more often choose the low-reliability stimulus.

Moreover, they did so independent of being able to detect an orientation change in the low-reliability stimulus. How they must have accomplished this inductive conclusion was by detecting no change in the high-reliability stimulus, they weighted their decision based on information from the high-reliability stimulus and selected the low-reliability stimulus despite their inability to see any orientation change. This is an example of *inferential reasoning and decision making by exclusion* (see also chapters “► Reasoning by Exclusion”, and “► Meta-Cognition”). It is also an example of metacognition: “you know what you can detect and you know what you cannot detect.” These are complex, sophisticated cognitive processes, particularly so for nonhuman species like rhesus monkeys.

## Charles R. Menzel

Michael J. Beran

Department of Psychology, Language Research Center, Georgia State University, Atlanta, GA, USA

Charles R. Menzel was a primatologist and scientist in the making from as early an age as he can remember. He recounts that even as a child he had the opportunity to explore freely in the woods and rivers of Florida and Louisiana and that this led to early exposure to animals and his early interest in their behavior and cognition. He watched and kept wild and domestic animals and learned how to care for them and observe them as they developed into adults. His grandfather, Emil W. Menzel, Sr., was an amateur naturalist who had kept a vast

number of animals in his house (deer, pythons, pangolins, to name just a few) while raising his sons in India. His father, Emil W. Menzel, Jr., was a man of high creativity who could make just about anything interesting. He studied nonhuman primates as a research psychologist and took Charles to visit the lab buildings and apes of the Yerkes Laboratories of Primate Biology in Orange Park, Florida, many times before the age of seven. Charles lived in Japan in 1963 and 1964, and during that time his father took him to watch Japanese monkeys in the hills outside of Osaka. That was a highly impactful experience for Charles. The experience of living in another culture and being treated kindly as a foreigner made a lasting impression on him, as evidenced by his continued desire to work in different parts of the world.

As a teenager, Menzel spent time observing apes and monkeys at the Delta Regional Primate Research Center in Covington, Louisiana, and watched wild primates for brief periods in field settings (Kenya, Tanzania, and Saint Kitts). In Louisiana, he frequently observed a group of young chimpanzees inventing ladders and observed the experiments that his father was conducting on leadership and communication in the same apes. He recalls the excitement of meeting and engaging scientists who were colleagues of his father when they visited.

Menzel completed his B.S. in Zoology from Duke University in 1977. During his undergraduate study, he conducted several behavioral tests with tamarin social groups. The results of those studies indicated that tamarins had an acute ability to detect novelty and changes in objects within their structurally complex greenhouse environment. Menzel also conducted a senior thesis on head cocking behavior in tamarins at Stony Brook University and in gentle lemurs at Duke University, under the guidance of Kenneth Glander and Peter Klopfer. The data he collected indicated that head cocking behavior in primates is elicited primarily by novel visual stimuli, is most frequently seen in young animals, and serves primarily a visual function (Menzel 1980; Menzel and Menzel 1980). These efforts led to an opportunity to spend a summer doing comparative behavior

studies at the Brookfield Zoo in 1977. This was the first of two opportunities to work with the ethologist, Benjamin Beck. They later worked on studies of spatial orientation in golden lion tamarins during 1989–1991 at the National Zoo (Menzel and Beck 2000).

Beginning in the 1960s, William Mason, Hans Kummer, and Emil Menzel, Jr., had developed and articulated a broad comparative approach to primate behavior. They shared what Mason called a “naturalistic bias,” taking as a primary source of data and research problems what animals do under everyday conditions. Charles Menzel absorbed all of their writings, along with those of Niko Tinbergen and the ecologist Peter Rodman, and decided to go to UC Davis for graduate school and conduct Ph.D. research under Rodman and Mason, who both exemplified the ideals of scholarship and careful analysis. They encouraged Menzel to develop a perspective – a logical or heuristic scheme – that could guide his research across future settings and years. Menzel grew interested in the ways that primates learned and discriminated categories of environmental structures and assigned value to them. This included the issue of how animals learned associations between types of food items and classes of environmental features, locations, time periods, and situational variables. It also included the problem of how well animals recalled events – food discoveries – that had occurred in areas out of view from the current location, and the stimulus factors that could facilitate remembering and appropriate search patterns. His discussions with Michael Andrews, Gustl Anzenberger, Leo Berenstain, Jane Gagne, Theodore Grand, Robert Lickliter, and Sally Mendoza were particularly important in helping him formulate these ideas during graduate school and beyond.

After completing his Ph.D. in 1986, Menzel was awarded an NRSA postdoctoral grant to study the complex interactions between primates and their environments in a field setting. Kummer served as his postdoctoral advisor. Naosuke Itoigawa invited Menzel to work at the Minoo and Katsuyama prefectural parks, where Osaka University maintained field research sites. Itoigawa had been a pioneer in studies of Japanese monkey social behavior. Menzel’s research

focused on this question: where does a free-ranging monkey go after it finds a single piece of experimentally introduced food, and what does this imply about its memory and the inferences that it forms? He found that the macaques responded very differently according to the type of food item discovered. If the food item was of a type that occurred naturally in the home range, this discovery appeared to reactivate a memory of something specific and an appropriate search “routine,” as if the animals knew that the type of food could be found in particular classes of environmental structure. For example, when finding akebi fruits that typically occurred in vines above the ground, monkeys stared upwards and entered trees that contained akebi vines. In contrast, if the macaques found a non-native food, such as chocolate, that had no history of association with the environment they instead searched near the location of the current find (Menzel 1991).

Kummer encouraged Menzel to pursue this mode of investigation with a captive colony of long-tailed macaques at the University of Zurich. This provided Menzel with an important opportunity to bring a behavioral phenomenon from the field into the lab for detailed study. Over a period of 6 years, he worked with Kummer and his colleagues, exploring social and ecological aspects of macaque learning and their ability to extrapolate their search beyond one or a few initial food items. They found that macaques used the close spatial proximity of a food item to a visible environmental structure as a cue to organize a wider search targeting similar structures. This was a form of innovative behavior, and it might be an optimal strategy for opening up a new food source under natural conditions. The macaques altered their foraging patterns in response to an unexpectedly wide range of stimulus factors and showed excellent memories for single events (Hemmi and Menzel 1995; Menzel 1996a, b).

This focus on single events, and memories of those events, played heavily in the next phase of Menzel’s career. He moved to Atlanta, GA, to work with Duane Rumbaugh and Sue Savage-Rumbaugh at the Language Research Center at Georgia State University, where he continues to conduct research and teach in the Department of

Psychology. He has collaborated on experimental studies of perception, cognition, and tool use in apes (chimpanzees and bonobos) and monkeys (rhesus macaques and capuchin monkeys) at the Language Research Center. He took a leadership role in establishing the research colony of capuchin monkeys at the Language Research Center which is now one of the largest colonies in the world. He developed a laser pointing device that apes can use to request objects and to pinpoint the locations of hidden objects. With Ted Evans, he developed training methods that successfully trained capuchin monkeys to use the laser pointing device flexibly and adaptively to request objects that lie beyond arm's reach.

At the Language Research Center, he also developed a novel and highly influential paradigm for using artificial language as a tool for studying recall and episodic memory in apes (Menzel 1999). The procedures are adapted as much as possible to the individual preferences of the ape. The work considerably extends the approach he used to study memory in New World monkeys and macaques, and it makes contact with current debates regarding the nature and extent of recall, episodic memory, and planning capabilities in nonhuman animals (Menzel 2005, 2010; Sayers and Menzel 2012). Menzel also has strongly contributed to empirical and theoretical discussions of the biological value and operation of primate cognitive capabilities in the natural habitat. His research includes efforts to assess prospective memory (Beran et al. 2012) and intentional communication (Menzel et al. 2002; Roberts et al. 2014). More recently, he has worked on problems of foraging and tool use (LaCour et al. 2014), navigation in simulated environments (Dolins et al. 2014), cognitive control (Beran et al. 2016), and risk sensitivity from a comparative and evolutionary perspective (Sayers and Menzel 2017).

Throughout his career, Menzel has received support for his research from a variety of sources, including the L. S. B. Leakey Foundation, the National Institute of Child Health and Human Development, the Wenner-Gren Foundation, the National Institute of Mental Health, the National Science Foundation (USA), and the Swiss National Science Foundation.

## Charles Robert Darwin

Robert Hutton

Oakland University, Rochester Hills, MI, USA

The chronology and information contained in this entry can primarily be referenced from two biographies of Charles Darwin. The information regarding Darwin's pre-voyage life and mid-voyage experiences can be found in *A Modest Genius: The Story of Darwin's Life and How His Ideas Changed Everything* by Hanne Strager (2016), and the post-voyage information can be found in *The Reluctant Mr. Darwin: An Intimate Portrait of Charles Darwin and the Making of His Theory of Evolution* by David Quammen (2006).

### Charles Darwin: Overview

Charles Robert Darwin was born February 12, 1809 – the fifth of six children born to Robert Darwin and Susannah Wedgwood in Shrewsbury, Shropshire, England. He attended the Anglican Shrewsbury School until the age of 16, when he would go on to study at Edinburgh University to

pursue a career in medicine. At 19, he began his education at Christ's College, Cambridge, at the order of his father. Here, he would engage in small game hunting and insect collecting. In 1831, Darwin set sail aboard the HMS Beagle as the gentleman companion to captain Robert Fitzroy. The Beagle was set to sail around the southern tip of South America, and on this journey, Darwin served as naturalist, collecting specimens from the rainforests and from a net towed behind the ship. After circumnavigating South America, the Beagle went west where it would famously stop at the Galapagos Islands before returning to England in 1837. During his years aboard the Beagle, Darwin kept detailed notes and journals that would later see publication and inform his theories.

After returning to England, Darwin went about his scientific business cataloguing his specimens and corresponding with various experts while writing his findings for publication. During this phase of his research, he and his colleagues noted the patterns of species variation as a function of their biogeographical circumstances. He would then spend the next 22 years developing his theory in various notebooks. *On the Origin of Species* was published in 1859.

Darwin married Emma Wedgwood in 1839. The couple would go on to have ten children, three of whom would die in childhood. The Darwin family lived in the small village of Down beginning in 1842, moving there to escape the political volatility of London. Darwin died on April 19, 1882.

### Early Life and Education (1809–1831)

Charles Robert Darwin was born February 12, 1809 in Shrewsbury, Shropshire, England. Charles was the fifth of six children born to Robert Darwin and Susannah Wedgwood. Darwin's father was a self-described freethinker and a physician with a passion for scientific undertakings such as chemistry and psychology. His paternal grandfather, Erasmus Darwin, was also a physician and authored *Zoonomia: or the Laws of Organic Life*. Charles began his studies at the Anglican Shrewsbury School, where he was

afforded a traditional education into his teenage years. However, in the early nineteenth century, science was not valued by the English educational system. This resulted in tension between Charles and his headmaster and classmates. At the age of 16, Charles was sent to Edinburgh University to study medicine at the order of his father. It was there that he would learn the fundamental scientific principles that would later inform his most influential and iconic theories. Even still, Charles' relationship with his father was complicated by his father's expectations.

Robert Darwin's fervor for science and propriety was at odds with Charles' passion for small game hunting and insect collecting. Robert was disappointed with his son's interests, going so far as to scold Charles explicitly, saying that he would be a "disgrace" to himself and the Darwin family. Robert served as an authority, emphasizing discipline in his otherwise aimless son. Susannah passed in 1817 from an unidentified gastrointestinal illness, so Charles was mostly cared for by his older sisters and maids. Robert's opinion of Charles would not change until he had established his career as a naturalist, travelling the world and conducting scientific observation. The initial seeds for this endeavor were planted during Charles' time at Edinburgh University where he was exposed to sciences that were not presented in more traditional schools.

In the beginning of the nineteenth century, traditional Anglican schools such as Oxford and Cambridge would not allow certain theories to be discussed. In fact, so-called radical students who doubted the divinity of humanity over nature were denied degrees and their lectures censored. This is why Edinburgh attracted many dissenting scientific minds – minds to which Charles was exposed during his time as a student there. One such scholar to whom Charles had attached himself was Robert Edmond Grant, a student of Jean-Baptiste Lamarck. Grant was among the first to echo Charles' sentiment regarding the origins of complex species. Both Grant and Darwin believed that biologically primitive creatures such as the sea slugs they had collected could inform upon the processes by which complex creatures had developed. This was where Charles began his study of

marine invertebrate zoology, a readily welcomed change of course for one who was so repulsed by the bloody business of human anatomy and surgery. However, his father was not satisfied with this education or direction. Naturalists, Robert thought, were more suited to be educated by the church.

At the age of 19, Charles began his education at Christ's College, Cambridge. This represented a drastic change in his educational environment. Whereas Edinburgh University was characteristically populated by academic dissenters and radicals, Cambridge was an institution that banned such dissenters. Moreover, Cambridge did not challenge Charles. While he learned botany and anatomy, he was free to indulge in his aimlessness. Here, he would drink, hunt small game, and collect beetles with his friends, just as he would at home in Shrewsbury. Charles did not forget the passions that were instilled in him at Edinburgh, though, and he eagerly accepted his botany teacher's suggestion of traveling to the southernmost point of South America aboard the HMS Beagle.

### **The Beagle (1831–1836)**

At the suggestion of his botany teacher, John Stevens Henslow, Darwin embarked as the gentleman companion of captain Robert Fitzroy on the HMS Beagle. The initial purpose of the journey was to survey the land and establish trade relations in Patagonia, as well as to return Christianized natives to Tierra del Fuego. With Charles Lyell's *Principles of Geology* and some blank notebooks in hand, Darwin set sail aboard the Beagle on December 27, 1831. He was to accompany the captain as a gentleman companion. This was a welcome change in title for Darwin, as he would not be expected to engage in any medical practice during the voyage. Rather, he was free to embark on his own excursions to observe the local wildlife and take specimens for study. Despite the grueling seasickness, this voyage represented a uniquely inspiring transition in the young naturalist's life.

In January of 1832, the Beagle arrived at the Cape Verde Islands, and Darwin was torn between

his endless fascination with his scientific pursuits and his unrelenting seasickness. He towed a net behind the ship during the days at sea collecting plankton to be studied. In the following months, he explored the rainforests of Salvador and Rio de Janeiro, collecting specimens of invertebrates and birds. The wildlife in these areas inspired both awe and fear in Darwin, as he saw not only the beauty of their anatomies and behaviors but also the horrific results of the arms race between predator and prey. The very same aversion to witnessing pain that prevented his pursuit of a career in medicine was also present in seeing the natural mechanisms of tropical wasps hatching their larvae in live hosts. Nonetheless, Darwin continued to take extensive fieldnotes during his excursions, examining the geology and wildlife of the many lands visited by the *Beagle*. He would spend his evenings translating his fieldnotes into more detailed records in his notebooks. He also diligently kept a journal of his experiences, which would eventually become the *Journal of Researches* (1839; retitled *Voyage of the Beagle* in 1905).

In July of 1832, the *Beagle* continued southbound along the eastern coast of South America. Through the summer and into the winter of 1832, Darwin was witness to rebellions and genocides of native peoples in Uruguay and Argentina. Continuing south to Tierra del Fuego in December, Darwin encountered more natives in the southern jungles. These experiences inspired in Darwin a fascination with culture among humans. Specifically, he was intrigued by the development of such vastly differing cultures within one singular species. This was exacerbated by his familiarity with the Christianized natives that were among the ship's population. These individuals represented the possibility for change between such widely differing cultures. Cultural differences among humans was one of many questions Darwin ached to answer. He continued his observations between bouts of seasickness, filling his notebooks with hypotheses, questions, and musings throughout the voyage.

During Darwin's time along the southeastern coast of South America, he would unearth fossils of extinct megafauna that he would then transport

back to the *Beagle*. This became a favorite pastime for him as it represented a tangible window into the past. In those 2 years, he expanded the fossil records quite substantially. He also made note of the geological changes that resulted in the formation of the Andes Mountains. In January of 1835, he would personally witness the mechanisms at work as Mount Osorno on the southwestern coast of the continent erupted and raised the land with it. As he had read in Lyell's book, these geological changes were constant and persistent, and they explained how fossils of seaside plant and animal species could be found at such altitudes in the mountain range. At the rates of geological change about which Lyell wrote and which Darwin witnessed, it would take thousands of years for such specimens to reach such heights. By thinking of natural processes as occurring over thousands of years, Darwin was able to expand his view on the natural processes of the development of species. However, he would not fully conceptualize this theory until after the *Beagle* landed back in England. Meanwhile, the ship was set to leave South America and explore the islands to the west.

In September of 1835, the *Beagle* departed from Peru and began its journey west. This is when the ship landed at perhaps its most famous destination: the Galapagos Islands, a chain of volcanic islands populated by prisoners. Here, Darwin collected specimens of what he believed to be several species of songbirds including orioles, wrens, and grosbeaks, many of which he neglected to label. He also made notes of the local tortoise species, some of which joined the crew of the *Beagle* as pets. Though he made note of physiological differences in the species by island, he would not realize the significance of such differences until his theory started to take shape back in England.

As the *Beagle* continued its journey west into the Indian Ocean, Darwin made note of the presence of coral reefs on mountains, speculating that their presence was the result of geological shifts similar to those he witnessed in Chile in the previous winter. Meanwhile, Darwin continued to deal with the hardships of life on the *Beagle* – those of seasickness, unsteady ground, and

cramped quarters. Moreover, he was preoccupied by the questions left unanswered during his years abroad. He wondered about the comparative physiologies of the birds on the neighboring islands in the Galapagos chain, about the extinction of megafauna in Argentina and Uruguay, and about the presence of marine fossils high in the mountains. This preoccupation inspired feverish note-taking during his final weeks aboard the *Beagle* and still would not result in a finalized theory until much later. Despite his lingering questions, he was nonetheless gladdened by the prospect of returning to the solid, dry, familiar grounds of England.

### **Life After the Beagle Voyage (1836–1837)**

Darwin's scientific reputation had preceded him in England before the *Beagle* landed in Falmouth, Cornwall on October 2, 1836. His letters had been distributed to scholars by his former teacher, John Stevens Henslow. He was kept busy by the work still left to do compiling his notes and specimens. The young man who left on the voyage was quite different from the man who returned. This difference was one of the first observations made by his father upon his return home. Robert welcomed his son home excited to see that the formerly aimless small game hunter had adopted and fortified a scientific fervor akin to his own. Following visits home to Shrewsbury and Cambridge, Darwin eventually settled in London, a short walk from the British Museum and the Zoological Society where he had sent crates of his specimens over the course of the *Beagle*'s voyage. His new priority was to collect these specimens and get them identified by the experts in the field. Luckily, because of Henslow's bolstering, Darwin already had some standing in scientific crowds despite his spending the last 5 years travelling around the globe aboard the *Beagle*. This standing made his correspondence with the ornithologists and geologists charged with identifying his specimens much easier than it would have been as an amateur naturalist. While his specimens were sent to their respective experts, Darwin was charged with

publishing a record of the *Beagle*'s voyage by Captain Fitzroy.

While Darwin began excitedly drafting his book using the diary that he had kept aboard the *Beagle*, he settled into the quiet life of a London scientist. He attended meetings of the Zoological Society and the Geological Society, joined social circles of political writers and historians, and even met with Charles Lyell whose book kept him company in his confined cabin during his voyage. Reading, writing, and discussing scientific theory was a refreshing change of pace for Darwin. Just 4 months later, these social connections would reveal to Darwin that he was on to something more scientifically significant than he had realized during his adventures in South America.

In January of 1837, Darwin heard the report from John Gould, the ornithologist charged with identifying the poorly labeled specimens collected from the Galapagos. What Darwin assumed were wrens, orioles, and grosbeaks were, in fact, all finches. During a follow-up meeting with Darwin in March, Gould further informed him that he had collected specimens from 13 new species of finch. They noted discrete morphological distinctions. Namely, the species could be distinguished by the shape of the beak. Unfortunately, Darwin neglected to properly note on which islands he had found each specimen. However, Gould also noted three new species of mockingbirds that were labeled by island. A pattern was now evident, as each species was distinct to a separate neighboring island. This pattern brought into question the stability of species, as it appeared that these animals were morphologically distinct based on the circumstances available to them in their separate environments. Meanwhile, the results of other specimens raised similar questions. The fossils of extinct megafauna that Darwin had collected in Argentina and Uruguay were identified as giant armadillos, capybaras, and ground sloths – all of which were found in regions inhabited by the non-giant versions of the species. Moreover, the reptilian specimens including iguanas and tortoises were also shown to have island-specific differences. As more and more identifications were made in the analyses of Darwin's collected specimens, the evidence

seemed to point toward species instability as a function of environmental necessity.

Darwin was cautiously coming to the conclusion that species change over time, and this was not the first idea of this ilk. He had heard of progressive change in species during his time at Edinburgh University from Robert Grant, a former student of the French zoologist Jean-Baptiste Lamarck. However, the idea that a species can change over time opposed the traditionally taught creation myth of Christianity, the official religion of England at the time, which had not yet been divorced from the scientific culture. After his meetings on finches, giants, and iguanas, he was beginning to believe that species could change, though he lacked a mechanism or process by which this would occur. Despite Darwin's personal development that occurred during his arduous trip around the world, he was not so emboldened as to come forward with this sacrilegious theory before developing it more fully.

### Development of the Theory (1837–1859)

Prioritizing clarity, Darwin began scribbling thoughts into a new notebook, labeled simply, "B." He started by reviewing his grandfather's medical book, *Zoonomia*, and found that Erasmus had also speculated on the origin of species. Erasmus had suggested that all warm-blooded species shared a common ancestor, though this claim was not reinforced with sufficient evidence. He also found that Erasmus was intrigued by the importance of sexual reproduction and the mechanism by which individuals of the same immediate family were able to differ from one another. Darwin went on to question what the eventual effects of such individual differences would be, arguing that species necessarily change. Notebook "B" contained Darwin's personal development toward these ideas, as well as principles from geology, zoology, botany, and biogeography, all of which were used to come to his conclusions. At the time, he referred to this change as "transmutation."

While Darwin quietly developed his theory and finished his Beagle manuscript, he shrank away from his social circles and began the sizable

endeavor of editing a new multi-volume collection of writings from assorted experts that would be titled *The Zoology of the Voyage of the H.M.S. Beagle*. In taking on this project, he continued to contribute to the very scientific culture that he was afraid would blacklist him as a radical for his private thoughts. These thoughts he carefully kept hidden in Notebook "B" and then later in Notebooks "C," "D," and "E." Meanwhile, he continued to take in information from the fields of agriculture, natural history, and animal and plant breeding. He talked with his father, with farmers, and with explorers. Remembering the principles about which Charles Lyell wrote in *Principles of Geology* and which he witnessed during the eruption of Mount Osorno, Darwin knew that the changes he was predicting would likely be exceedingly gradual. If a species were to change fully into a new, distinct species, thousands and thousands of years would be necessary. As Darwin's confidence in the evidence he had compiled grew, his health deteriorated steadily. His notebooks, however, illustrate the determination Darwin had to develop his theory in pursuit of scientific understanding.

Darwin's health became a significant issue that seemed to coincide with the development of his theory. In September of 1837, he began to note heart palpitations, vomiting, headaches, and anxiety. At a doctor's order, he began to reduce his time spent in his scientific pursuits in favor of a more restful life. In letters, he specified the stimuli that triggered episodes of palpitations and anxiety. This list included social events, conversation, and conflict. He spent some time at home in Shrewsbury to help alleviate the symptoms that seemed to come with the stress of his scientific pursuits. It was at this point in his life that he began to consider starting a family of his own, despite his responsibilities including the compiling of the massive volumes of zoology from the Beagle and continuing to document the crates of specimens sent back from his voyage.

The prospect of starting a family introduced two new sources of anxiety for Darwin: marriage and money. To this point, he had been living fortunately from the allowance sent to him by his wealthy father, who did so in order to allow

his son to pursue his scientific exploits. This was a boon that Charles himself specifically noted as a fortunate circumstance that allowed him to write the manuscript of the Beagle's voyage. Although this allowance was enough to continue the life he was living, it would not be enough to sustain a wife and children as well. Darwin thought out his decision as scientifically as he could, by writing out the pros and cons of marrying or not marrying. This and his theories would demand his thoughtful attention for months. In June of 1838, he sought to escape his responsibilities by travelling to Scotland to carry out geological fieldwork. On his way back to London, he visited his family in Shrewsbury where his father assured him that he need not worry about money or marriage. Continuing back toward London, he also visited his cousins, the Wedgwoods, one of whom he would later marry. With the issue of marriage weighing on him, Darwin continued to ruminate over his theories.

In Notebook "D," Darwin extensively considered the work of Thomas Malthus, an English scholar who published the *Essay on Population*. In this essay, Malthus described species' tendency to reproduce beyond the limitations of their available resources. His logic was laid out arithmetically, illustrating that populations grow by multiplication, not by addition. Because of this property, populations can quickly outgrow their means, resulting in competition and eventual starvation. Darwin, still seeking the mechanism or process by which species can change over time, ruminated over Malthus's arguments as they applied to nonhuman populations. Darwin began to think of competitive advantages between individuals for the various challenges faced in nature. If a population outgrew the available resources, which of them would be able to take advantage of the available resources? Which individuals would be more likely than others to be caught by predators? The answers, Darwin knew, could be found in those individual differences that result in differential survivability. He would later describe this process as "natural selection." This framework represented a promising development in his theory and served as a springboard to Notebook "E." Around the same time, he began writing of tangential questions in Notebook "N."

Additionally, around this time, he travelled home to ask Emma Wedgwood to be his wife. The two were married on January 29, 1839, and left immediately for London so he could continue his work.

Between 1839 and 1842, Darwin had developed his theory, his career, and his family. He published his *Journal of Researches* in 1839, and that was met with notable success. Additionally, Emma had given birth to their first son, William, in December of 1839 and their first daughter, Anne, in March of 1841. In 1842, the climate in London had become so politically volatile that Charles and Emma decided that it was time to move to the countryside – a small village called Down. That summer, Emma gave birth to a second daughter, Mary, who would only live 3 weeks. After moving to Down House, Darwin indulged in the seclusion, only travelling to London occasionally and instead relying on letters to correspond with his colleagues. In 1843, he would begin correspondence with botanist Joseph Hooker.

After Hooker's own nautical voyage as a naturalist, he had agreed to study the plant specimens that Darwin had collected while aboard the Beagle. In studying Darwin's plants, Hooker also noted the variation between plants found on separate neighboring islands. Seeming to grow impatient with his withholding of the conclusions he had drawn, in January of 1844, Darwin wrote his theory in a letter to Hooker. In doing so, Darwin also noted that his conclusions were distinct from Lamarck's unsupported theories of progression. In response, Hooker began studying Darwin's Galapagos plant specimens with a new framework in mind, and Charles began his work addressing the process by which a species might change.

With the logic of his theory finally articulated, Darwin set forth with a new sense of motivation to investigate the plausibility of his proposed mechanism. As he began putting his theory on paper and, with nearly 200 pages already written, he instructed Emma to ensure that his work would be finished and published if he were to pass before finishing. His vomiting and headaches would still return sporadically, after all, making his health a noteworthy concern. The shortlist of scholars who could be selected to finish his work included close friends such as Charles Lyell, Joseph Hooker, and Robert Grant. As Darwin himself became bolder,

vocalizing his conclusions in writing to other scholars, other theoreticians were at work. In October of 1844, an anonymous author published *Vestiges of the Natural History of Creation*, a volume of scientific writings addressing many of the same issues about which Darwin had been ruminating for nearly a decade. The volume proved to be very successful, read by scholars and laypeople alike. However, unlike Darwin's theory, *Vestiges* argued that the transmutation of species was a function of a divine hand and that humans were preordained by that hand as the superior species. Darwin was vocally unhappy about this new publication, though he knew that it could pave the way for a more developed and scientifically rigorous theory like his own. In any case, his growing confidence was shaken, and he turned his attention back to the *Beagle* geology and zoology volumes.

At this point in his life, Darwin became much quieter than he had been in previous years. The confidence he had garnered from his developing theory had waned drastically. His publications since disembarking from the *Beagle* had seen mild to moderate success, and he had made a name for himself among the scientific community. He set about revising new editions of his publications and otherwise kept to himself. In these publications, it was clear that Darwin had edged fairly close to his broader question of species' change over time and the function of environmental conditions in the process. On October 1, 1846, just shy of a decade after the *Beagle* landed in Falmouth, Darwin finalized his writings on the geology of South America and began working on his last sample of barnacles collected in the Galapagos. Barnacle taxonomy would then demand his complete attention until 1854. In his 8 years agonizing over barnacle anatomy and physiology, dissecting and investigating specimens collected from all over the globe by his contacts, Darwin had fostered a sizable network of scholars. During this period, he experienced the stresses of the project, of academic poaching, and of the death of his father in 1848, all of which exacerbated his stress-related health problems. During his travel back to Shrewsbury for his father's funeral, he wrote an apology for his chronic unwellness in a letter to his wife.

Darwin's barnacle work slowed as he focused on his health problems. He engaged in a combination of homeopathic treatments and a water-based method meant to draw blood away from his stomach at the order of Dr. James Gully. The treatments worked, and Darwin began to cut his working hours in order to reduce his stress. Slowly but surely, his barnacle work progressed until his daughter, Annie, had become ill. After a bout of scarlet fever in 1849, Annie had yet to fully recover, and several months later, she had begun presenting with similar symptoms to those chronically experienced by her father. Annie was then sent with her younger sister, Henrietta, to Malvern to receive treatment from Dr. Gully. When her condition worsened, Charles went to her side. Annie passed in April of 1851, and 2 days later, Charles was back in Down to mourn with his then-pregnant wife. It was during this time that another naturalist was independently coming to conclusions very similar to those that Darwin had drawn in his lettered notebooks.

Alfred Wallace, a young, uneducated, middle-class naturalist embarked on his own voyage exploring the Amazon. Wallace was well-read, having studied *Vestiges of the Natural History of Creation* and Darwin's *Journal of Researches*, among many other works that inspired his exploration and his theories. Wallace's journey began in 1848. Unfortunately, a fire aboard the ship bound for England destroyed the specimens in 1852. He was able to save some of his notes and sketches, but he lost everything he had spent the last 4 years collecting. After the life-threatening journey, Wallace arrived back in England in the summer of 1852. Despite his newly developed aversion to sailing, he began to plan another expedition in order to resolve the unanswered questions regarding the progression of species. After his journeys, Wallace began publicly discussing his theory on progressive development, unaware that Darwin had developed similar theories in secret.

Wallace's presence in the scientific community sparked in Darwin a pressure to vocalize his theories more clearly and with more support than he had in the past. He began testing the mobility of plant seeds to see if it was possible for them to survive a journey to a new island in the digestive system of a bird. He began to ask his contacts for

specimens of bird and mammal bodies that he could then dissect and compare. He began breeding his own flock of pigeons to examine the effects of selective breeding. He set out to figure out what caused variation as a naturally occurring phenomenon in reproduction of both wild and domestic species. His theory, after all, rested upon the notion that differing environments would naturally possess distinct selective pressures resulting in change in a species over time. Wallace's theory was published in 1855 with no substantial uproar in the scientific community. It was enough, however, for Darwin's colleagues to encourage him to publish his more developed theory.

In the summer of 1858, Wallace had written to Darwin about his new breakthrough. He told Darwin about his idea whereby species change due to the inherent struggle to survive as a species grows beyond its resources. Essentially, Wallace had come to the same conclusion as Darwin whose book was still incomplete. Darwin was significantly unhappy with this development, knowing that if he had not taken so much time to develop his theory, he could have been the first to publish. Suffering through the death of another child and his persisting illness, he continued to correspond with his colleagues who encouraged him to continue working on his book. When it came to the presentation of these ideas, Wallace was given partial credit. He was content with this arrangement as a younger and relatively less educated naturalist, as this meant he was welcomed into the scientific community paired next to Charles Darwin himself. In May of 1859, Darwin's writing was finished, and in November, *On the Origin of Species by Means of Natural Selection*, would be in high demand days before its official publication.

### **After *Origin* (1860–1882)**

For the most part, Darwin's assertion that species have descended from common ancestors through change over time was widely accepted. The argument that many biologists took issue with was that of natural selection being proposed as the primary driving force behind such changes. This was due to the prevalent natural theology whereby evolution occurred by a divine hand. Darwin's

arguments suggested no intentionality of the variations that naturally occurred; variations were simply the result of selective pressures in the environment. Among theological scientists – including those who formerly taught Darwin the foundations of his scientific education – the book was panned as overly materialistic. In the commentaries and critiques published in response to *Origin*, the concept of natural selection was brought into question frequently. Even Alfred Wallace would argue a limit on the scope of natural selection as a process by asserting that it could not have resulted in the human brain. Meanwhile, zoologists, biologists, and geneticists were exploring the mechanisms of inheritance, further informing Darwin's arguments regarding variation. Regardless of these theoretical developments, Darwin felt a substantial relief now that his theory was essentially out of his hands, published, and no longer a secret in need of such meticulous development.

Darwin's health began to improve without the stress of his book weighing on him. He produced several more editions of his publications but otherwise kept to himself. With each edition, he addressed some criticisms and adjusted his language accordingly. Over the years following the publication of *Origin*, he had resolved to avoid being as provocative as he had cautiously been in the past. In 1875, he published *Insectivorous Plants* with the help of his sons, Francis and George. This volume was far less provocative by design, and thus did not perform as well as *Origin* did. Emma took to caring for her elderly husband in the late 1870s. In 1876, hearing the news that Francis' wife was pregnant, Charles began to write his memoirs. He was very close with his new grandson, Bernard, through the rest of his life.

In 1881, Darwin began to experience more heart problems. On April 19, 1882, he passed fitfully of degenerative heart failure. Because of his contributions to science, he was buried in Westminster Abbey along with his close friend and colleague Charles Lyell who had been interred there in 1875. In his final days, Darwin finished more work on the beetles that he loved to collect and how they dispersed across territories. "On the Dispersal of Freshwater Bivalves" was his last publication, appearing as a note to *Nature* just 13 days before

his passing. In this, Darwin discussed the likelihood with which a larval mollusk might adhere to water beetles who would then fly them to new bodies of water. In this last publication, Darwin added more support for his theory on the process of evolution by natural selection.

## Publications by Charles Darwin

- 1839 – *Journal of Researches into the Geology and Natural History of the Various Countries Visited by H.M.S. Beagle, Under the Command of Captain FitzRoy, R.N. from 1832 to 1836*. London: Henry Colburn.
- 1839 – “Observations on the Parallel Roads of Glen Roy,” *Philosophical Transactions of the Royal Society of London*, 39–81.
- 1842 – *The Structure and Distribution of Coral Reefs. Being the first part of the geology of the voyage of the Beagle, under the command of Capt. FitzRoy, R.N. during the years 1832 to 1836*. London: Smith, Elder.
- 1851–1854 – *A Monograph of the Sub-Class Cirripedia*. Vol. I: *The Lepadidae, or Pedunculated Cirripedes*, 1851. Vol. II: *The Balanidae, (or Sessile Cirripedes); the Verrucidae, etc.*, 1854. London: The Ray Society.
- 1851–1854 – *A Monograph of the Fossil Lepadidae, or Pedunculated Cirripedes of Great Britain*, 1851. *A Monograph of the Fossil Balanidae and Verrucidae of Great Britain*, 1854. London: Palaeontographical Society.
- 1859 – *On the Origin of Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life*. London: John Murray.
- 1862 – *On the Various Contrivances by which British and Foreign Orchids are Fertilised by Insects, and on the Good Effects of Intercrossing*. London: John Murray.
- 1868 – *The Variation of Animals and Plants Under Domestication*. London: John Murray.
- 1872 – *The Expression of Emotions in Man and Animals*. London: John Murray.
- 1875 – *Insectivorous Plants*. London: John Murray.
- 1875 – *The Movements and Habits of Climbing Plants*. London: John Murray.

- 1877 – *The Different Forms of Flowers on Plants of the Same Species*. London: John Murray.
- 1881 – *The Formation of Vegetable Mould, through the Action of Worms, with Observations on Their Habits*. London: John Murray.
- 1882 – “On the Dispersal of Freshwater Bivalves,” *Nature*, vol. 25, April 6, 1882.

## Definition

Cheating is a behavior by which a person intentionally tries to reach a goal by breaking the rules or through immoral procedures. The cheater is characterized by trying to obtain undeserved advantages and acting from their own interests.

## Introduction

In the framework of social, cognitive, and evolutionary psychology, cheating is a complex form of social interaction according to which one person intentionally introduces one set of false beliefs into the other, for personal gain (Rivière 1991). Cheating always includes a deliberate manipulation of the behavior of others. This manipulation occurs through the introduction of a false belief in others by adulterating information for personal benefit (Perner 1991).

Cheating behavior is based on a human cognitive system through which the person recognizes that he/she has a mind and also attributes it to others; this act of “mentalization” is complemented by consciousness, corresponding to the attribution that their actions are intentional (Rivière et al. 1994). The conceptual system that serves as the basis of cheating and manipulation has received the name of “Theory of Mind” (ToM). ToM is all that cognitive framework that permits to the human beings distinguish their view of the world from the view of others. By means of ToM, the humans can define and distinguish mental status in themselves and in others, and also predict or influence in its behaviors (Premack and Woodruff 1978).

## Phylogeny

From the phylogenetic point of view, one of the pioneers in the study of the cognitive mechanism of the ToM is Humphrey (1976, 1983) who formulated the hypothesis of “social function of intellect”; according to this hypothesis, the social intelligence has an important role in the development of the human mind. The research of this author was based on observation of no-human

primates. Humphrey (1983) reach the conclusion that primates are smarter than other animals because in its evolutionary process, they have had to face social problems as fights for power or for mating and the solutions to this problems requires alliances or cooperative strategies. Other strategies may include manipulate others, for example, a chimpanzee that, to be able to mate, cheats to a competitor offering him food to distract his attention; in this moment it can be said that the behavior of cheating was born, phylogenetically speaking.

In a more recent research, Fehr and Fischbacher (2004) support the idea that humans have evolved by the branch of psychosocial development rather than by the physical control of the environment; this characteristic has separated them from the other primates, because the psychosocial development has allowed human to control deception and increase cooperation. This particular type of development has been consequence of a combination between self-consciousness and ToM.

From this perspective, deceive behaviors are related with the intentionality of human beings; the person not only have to be conscious of his own mind but also to know that others have mind. Humans, unlike others primates, has the capacity of form and use consciously the ToM which for some authors (McCabe et al. 2000) is at the basis of human phylogeny.

Rivière and Nuñez (1994) have shown that although in nonhuman primates and in young children (under 4 years) there are situations of deception, they are not generated from the intentional introduction of false beliefs in others to obtain personal benefits (which are characteristic of the human development of the ToM). As a result of this research, the authors conclude that cheating in the early ages and in primates occur as a consequence of the detection of intentions in the others and the manipulation of this intentions.

## Ontogeny

From an ontogenetic point of view, the capacity of mentalization is progressively developed in the

period between 1 and 5 years of age, approximately (Wellman et al. 2001). At this age, the child acquires the complete cognitive system that allows him to differentiate his mind from that of others; those system includes the important notion of “false belief” (Wimmer and Perner 1983). Although with some controversy (Bloom and German 2000), the false belief is one of the widely used criteria to determine if a person has the capacity of deliberately transmitting to another person a mistaken belief in order to obtain a benefit. This ability to deceive is an indicator of the develop the ToM and, joint with a conscience of its own actions, a child will be able to detect or produce a deception, a trap, or a lie.

The ability of cheating constitute an indicator of the mentalization because at this point the child understands the mind as a belief system that can be used for manipulate others for his own benefit, but simultaneously, the child also understands that others also have a system of mental representations and therefore can manipulate and deceive (Rivière 1991).

Other indicator used to detect the ToM in children is the tactical deception. This concept may be defined as the capacity to modify part of the repertory of behaviors to adapt it to a cheating role (Riviere and Nuñez 1998). Again, some controversy between authors was found. On the one hand, some researchers as Perner (1991) consider that cheating is atypical among preschoolers, and other (La Frenière 1988; Hoogenraad and McKenzie 1995) considers that cheating is a common and spontaneous behavior in children’s behavior and that it is a valid criterion for measuring the ToM.

Hoogenraad and McKenzie (1995) developed a measure to evaluate the ToM in small children by examining its deceive capacity. The model propose three steps in the development of cheating, the first is related to the manipulation of behavior through learned strategies, for example, to cheat to avoid a punishment. The second stage is characterized by a comprehension of mental states. In this phase appears the concept of false beliefs and the understanding of the intentions of others. The children has access to this information that allows it to deceive. The third stage,

developed in elder children, its related to the use of cheating with altruistic purposes. According to Rivière and Nuñez (1994), between age of 4 and 5 a child may recognize that a behavior comes from a belief and this, in turn, comes from an information source, coinciding with the second stage proposed by Hoogenraad and McKenzie.

Some authors (Astington and Gopnik 1991; Bruner 1990) agree on the relevance of the social and cultural context in the mentalization process. According to this view, the child’s understanding and awareness of the representations of his/her own mind and those of others is a social process transmitted through cultural ways, the same occurs with the ability to deceive.

## Major Advances and Applications

### Mirror Neuron System

One of the major advances on the last years that has allowed to deepen in the origin and the nature of the deception is the discovery of the mirror neurons in the premotor cortex and in the parietal lobe of the primates (Gallese et al. 1996). During the last two decades, two neural systems involved in personal interactions have been discovered. On the one Hand, the Mirror Neuron System (MNS) that allows to understand the imitative actions and behaviors and, on the other hand, the “mentalization system,” which has allowed the anatomical definition of the ToM, locating it in the precuneus, the temporoparietal junction and the medial prefrontal cortex (Van Overwalle and Baetens 2009).

The relationship between both systems is now under discussion because there is still no complete explanatory paradigm that confirms the activation of mirror neurons in complex situations of cheating (Agnew et al. 2007; Schippers et al. 2010).

What has been found so far in that the MNS is activated when a subject executes an action, and when observing others executing an action (imitation), this activation occurs in both primates and humans, which share very similar mirror neurons. In spite of these similarities, the reaction to the deception is different as found in some experiments with simple deception situations. For

example, in an experiment in which the task was to collect a caramel, the mirror neurons are activated in both primates and humans when candy is indeed present, but in situations where there is no candy (cheating), only the mirror neurons of humans are activated. Through this experiment, it is shown that in the evolutionary process human primates, being immersed in situations of very complex social interaction, developed the capacity to deceive and that this capacity has a neurological correlate in the MNS.

### Variables Associated with Cheating

There is an increasing interest in knowing and deepening the origins of cheating interactions and the mechanisms that help to mitigate them. There is also a broad interest in deepening the characteristics of the cheater. For example, it has been investigated whether personal characteristics such as gender, socio-economic status, or age influence the tendency to deceive.

Regarding the influence of gender, some studies have shown that men report a more favorable attitude to deception and also a greater propensity to engage in deceptive behavior, although the differences vary according to the scope, method of data collection, and country. A meta-analysis by Whitley et al. (1999) based on 48 studies related to attitudes and misleading academic behavior has shown that there are differences in attitude between men and women although the size of the effect has been moderate ( $r = 0.21$ ), with respect to cheating behavior the effect size is even lower ( $r = 0.08$ ).

Houster et al. (2015) have focused on the study of acts of dishonesty including parents and children. In this study, they have found that there are higher levels of deceit when parents are not with their children and when deceit benefits children more than their own parents; in the presence of children, parents act more honestly but there are differences in gender: parents act deceitfully in front of their sons more often than in front of daughters.

Regarding socioeconomic status, research converges to find that people with higher status have

more favorable beliefs towards the deceive and are more likely to commit acts of dishonesty, such as cheating to win a prize (Piff et al. 2012).

With respect to age, some studies have focused on analyzing cheating behaviors in young children, in an experimental study by Kotaman (2017), conducted with children between 4 and 6 years; it is concluded that children who are offered a reward for solving a task (puzzle) tend to perform more traps than children who are not offered reward. The authors have also found that cheating behavior was not related to parenting styles. On the other hand, Pan Ding et al. (2014) studied the cheating behavior in children of elementary school, between 8 and 12 years of age, they found that cheating behavior decreases with age and that executive function has a double influence on deception; on the one hand, its development inhibits this type of behavior and, on the other, it makes the cheating mechanisms more sophisticated.

### Cheaters Detection in Social Interaction

An topic widely studied by evolutionary psychologists (Sperber et al. 1995; Liberman and Klar 1996; Carlisle and Shafir 2005) is the detection of cheaters in social interaction; this authors frame the research in the context of the social contract theory. This theory postulates that humans have a cognitive architecture that enables them to detect cheaters in contexts of social relationships. The postulates of the theory have been tested by the Wason's task of selection, in which it has been proven that people have developed module of "detection of cheaters" that causes them to detect them automatically in scenarios of social exchange.

Recently a study by Van Lier et al. (2013) revised this automatic character of the "detection of cheaters" using the selection task, the authors established that the performance in the versions of the social contract did not depend on the cognitive capacity nor the age and that the experimental burden of cognitive resources with a secondary task had no impact on detection in the social contract. However, in all experiments,

performance in a nonsocial contract version depended on the available cognitive ability. In general, the findings validate the automatic and effortless nature of social exchange reasoning.

On the other hand, numerous experiments have been carried out on memory and facial recognition of cheaters; however, no conclusive results have been found. Buchner et al. (2009) have found that source memory is increased but not recognition memory. In contrast, Yamagishia et al. (2003) find that if there is greater facial recognition of individuals recognized as cheaters compared to those known as cooperators. Dellanrosa (1999) has found that people of high rank are more likely to detect deception in their subordinates than vice versa.

## Assessment of Cheating

One of the most interesting applications among scientists and professionals, especially in the area of legal psychology, is the development of measures of deception. There are three main strands in the study of these measures: on the one hand, psychophysiological techniques that are based on the measurement of vegetative-physiological activity (heart rate, blood pressure, respiration, skin conductance, dilation of the pupils, eye tracking, neuroimaging...); on the other hand, the study of verbal behavior (voice fluctuation, rapidity of responses, discourse analysis...); and finally, the analysis of nonverbal behaviors (behavioral observation, analysis of nonverbal behavior...).

The origins of the deception detection go back to the beginning of the SXX with the first measures of the blood pressures carried out by Martson (1917) who is considered the father of polygraphy. The next step was the development of the Relevant/Irrelevant Technique (RIT; Larson 1932) which compares answers to relevant questions with answers to irrelevant questions, RIT techniques have been criticized because the relevant question can produce physiological changes by the mere fact of having a greater emotional content. Due to this lack of validity of the RIT method, another technique called Control Question Technique (CQT; Reid 1947) was proposed.

CQT was based in generating irrelevant questions with greater emotional content. The CQT is a polygraph variant that has been used until now in different countries but in a more sophisticated way, with quantitative scores originally proposed by Backster (1962) and computerized scoring systems originally proposed by Raskin (1982).

In the 1960s, Likken proposes an alternative technique for the psychophysiological detection of deception, called GKT (Guilty Knowledge Test; Lykken 1960). This approach differs from the CQT because it does not use direct questions, instead it uses indirect questions about details of the event of interest (for example, a crime) that would only be known to someone who has been involved in it. Format of responses are multiple-choice and are based on the comparison of the options that provide pertinent information with options that contain irrelevant information.

A third approach to the study of the cheating detection is the Differentiation of Deception (DoD; Furedy et al. 1988). The study of the deception through the DoD consist in to ask the examinee a series of questions (they may be of an autobiographical nature) and instruct him to respond honestly to half of them and deceptively to the other half. Currently, this mechanism is used with some variants such as asking the examinee to answer the same question in a sincere and deceptive way; the last test format has been called SLT (Sheffield Lie Test; Spence et al. 2001).

Measurement techniques of the dependent variables (psychophysiological) also has changed through the time, from initial measurements based almost exclusively on blood pressure, respiration, and heart rate (basic measurements of the polygraph) to the use of modern neuroimaging techniques such as PET (Positron Emission Tomography) or fMRI (functional Magnetic Resonance Imaging). Last techniques were incorporated into scientific research on the 1990s (Farwell and Donchin 1991; Rosenfeld et al. 1991) and have been increasingly used by researchers interested in detecting deception (Gamer 2014; Ganis 2015; Meijer and Verschuere 2015).

Other measures recently used to detect deceive have been response times (Seymour et al. 2000), eye movements (ET, Eye Tracking, Schuetzler

2012), and detection by “expert judges” who are people with special abilities for the detection of cheaters (Vrij et al. 2006); last technique has been object of controversy (Bond et al. 2007; O’Sullivan 2007).

Despite the recent interest in measuring deception through more objective and sophisticated techniques such as ET, PET, and fMRI systems, there are still many doubts about the reliability and validity of the deception measurement process. In a recent review of existing literature, Meijer et al. (2016) concluded that most of the scientific literature that uses neuroimaging for the detection of deception has important conceptual and methodological problems. The most important of which is that there is no differentiation between the dependent variable and the approach for the evaluation (DoD, GKT, or RIT).

To conclude this section on the measurement of deception, it is important to mention the importance of other types of measurement, for example, the analysis of the verbal content of discourse, among which two approaches stand out: content analysis based on criteria (Masip et al. 2005) and the technique of reality monitoring (Alonso-Quecuty 1992; Vrij 2000). Nonverbal approaches that attempt to measure deception through behavioral indicators and observation of the behavior of the examinee are also important, emphasizing nonverbal cues as a basis for detecting deception (Zuckerman et al. 1981). Finally, it is worth mentioning the development of instruments to measure the attitudes towards cheating as proposed by Gardner and Melvin (ATC, 1988), who present in their article evidence of reliability and validity through a negative correlation between ATC scores and cheating behavior measured by a study guide.

## Academic Cheating Behavior

With regard to academic fraud, numerous investigations have been carried out in different areas of knowledge and also at various levels of education, especially in university students, specially in the last decades in which fraudulent behavior as copying on exams or plagiarism have been increasing

(Vandehey et al. 2007). Among the investigations found, it is worth mentioning the studies Perceptions and Attitudes toward Cheating among Engineering Students (PACES-1; Carpenter et al. 2002), in which it has been found that the behaviors of deception depend on the attitudes towards cheating, that is to say, those students with more permissive attitudes tend exhibit more cheating behavior.

Another common result in some investigations is the influence of the context (Diekhoff et al. 1996): several situational variables such as the level of studies, make fraud in secondary school, or the rationalization of the fraud by neutralization (e.g., to blame the teacher) have wide influence in the cheating behavior. Despite the wide influence of the context, there are psychological factors that condition the cheating behavior independently of the context, for example, certain types of personality facilitate or, on the contrary, deterrent the fraud. Some studies have found that students with greater morale and more shameful exhibit less fraudulent behavior despite the context (Finelli et al. 2003). On the other hand, some studies (Perry et al. 1990) have found that competitive students with high achievement motivation (Type A personality) tend to exhibit greater tendencies to fraud; however, other studies (Huss et al. 1993) refute this hypothesis not being clear yet the association between these variables of personality and cheating behavior. Finally, another area with interest are the development statistical indices for the detection of answers copied in exams (Wollack 2003).

## Conclusions

Although deception is a topic of great social and academic interest, much research is still needed to be done, especially, to implement the important contributions offered by the field of neuroscience. This chapter has addressed the phylogenetic and ontogenetic origins of deception, some major advances and applications, but not other applications that have been extensively studied in scientific research such as cheating in sports, in games, and in pair relationships. Several authors have

critiqued the literature about cheating behavior, because different studies have measured dishonesty in many different ways; therefore, it is a challenge for the future to design measures of deception more adjusted to the proposed theoretical models.

## Definition

Compounds used by organisms as a source of information to interpret environmental stimuli even though they did not evolve in the emitter for this function.

## Introduction

Organisms obtain information available in the environment through cues, which can be acoustic, chemical, electric, magnetic, tactile, and visual. Chemical cues are compounds used by organisms as a source of information to interpret environmental stimuli even though they did not evolve for this function in the emitter (see ► “[Evolution](#)” in this book). Numerous compounds of several chemical classes can act as chemical cues, including cuticular hydrocarbons (CHCs) and other molecules such as peptides and proteins (see ► “[Protein](#)” in this book). Like other cues, chemical cues can influence the behavior of a receiver and are sensed by all organisms that use them for varied aspects of life, such as orientation, location of food, nest sites or partners, threat detection, recognition of conspecifics, parental care, and

territorial defense (Stevens 2013; Nielsen 2017) (see ► “[Conspecifics](#),” ► “[Orientation](#),” and ► “[Territory Defense](#)” in this book). Chemical cues can indicate a suitable mating partner; provide information about the immune system, health or diseases, and food quality; and be used to recognize kin (Wyatt 2014; Nielsen 2017).

It is possible that chemical cues are the oldest form of obtaining information from the environment since even the earliest organisms had receptors for receiving and interpreting chemical cues and because of the enormous variety of compounds available in a potentially unlimited number of possible combinations (Wyatt 2014). Organisms detect chemical cues in the atmosphere and water and from the surface of other organisms or animate or inanimate substrates through olfaction (olfactory cues) and taste (gustatory cues) (Nielsen 2017; Elgar 2019).

Different from other cues, chemical cues require a physical interaction between molecules and receptors located in the sensory organs of the receiver and can transport information over considerable distances, although not as precisely targeted or as fast as acoustic or visual cues, for example (Wyatt 2014; Elgar 2019). Molecules acting as chemical cues can be volatile or involatile, soluble or insoluble, and large or small, depending on whether they are carried to the receiver in air or water; they can also, for example, be deposited on the sensory organ of the receiver, and be short or long range, or act on contact (Wyatt 2014).

Animals share similarities in the ways they use chemical cues, with several parallels in uses and sensory processes, which can be the result of evolutionary convergence or common ancestry (Wyatt 2010). Organisms can respond to chemical cues from individuals of the same species or from different species. A chemical involved in a chemical interaction between organisms is called a semiochemical. Semiochemicals that act between members of different species are called allelochemicals, of which there are various kinds, including allomones, kairomones, and synomones, which benefit the emitter, the receiver, or both the emitter and the receiver of different species, respectively (Wyatt 2014). Some

semiochemicals that act between members of the same species evolved for communication as chemical signals, such as pheromones, for example; other semiochemicals that act between members of the same species, or among different species, that did not evolve as signals can be exploited as cues (Wyatt 2014) (see ► “[Chemical Signals](#)” and ► “[Pheromone](#)” in this book).

## Chemical Cues and Signals

Distinguishing between chemical cues and signals is not always an easy task because it is context dependent and because a chemical may act simultaneously as a signal and as cue. For example, a pheromone (chemical signal) emitted by an animal to communicate with another member of the same species may act as a chemical cue for a predator that can identify it as belonging to its prey. A signal is any act or structure that influences the behavior of other organisms (receivers) and which evolved specifically because of that effect and functions because the receiver’s response also evolved (Stevens 2013; Wyatt 2014). However, unlike chemical signals, chemical cues did not evolve exclusively for that purpose in the emitter (Wyatt 2014). For example, humans eliminate carbon dioxide (CO<sub>2</sub>) through breathing, which mosquitos sense and use to locate human hosts to acquire blood. Thus, CO<sub>2</sub> works as a chemical cue since its elimination by humans did not evolve exclusively to modify mosquito behavior so as to find humans. Cues usually benefit the receiver but can also benefit the emitter, and since they did not evolve specifically to influence a receiver, they are not distinctive from the environment, and thus organisms must to be able to distinguish them from environmental noise (Stevens 2013).

Chemical signals, such as pheromones, may evolve from chemical cues that have been in the environment for other reasons long before any suitable receptors existed (Steiger et al. 2010; Wyatt 2014). Many molecules act as pheromones, which suggests that almost any molecule can evolve into a pheromone if it gives a selective advantage (Wyatt 2014). There are two main routes

by which chemical cues can evolve into signals: emitter preadaptations and receiver preadaptations. These involve, respectively, signals that start as chemical cues released by the emitter that can be sensed by the receiver and molecules that are selected by the receiver because they match its already existing sensitivity (Wyatt 2014).

## Signature Mixtures

Signature mixtures are chemical cues (a subset of molecules in an animal's chemical profile) that animals learn and use to recognize another as an individual (e.g., lobsters, mammals) or as a member of a social group (e.g., ants, bees, mongoose) and can also be used to recognize castes, conspecifics, and sex (Wyatt 2010, 2014). All signature mixtures are detected by olfaction, with the component molecules being produced by the organism itself, acquired from a shared local environment, or produced by other organisms (Wyatt 2010). In contrast to chemical signals, signature mixtures of animals, be they social insects or mammals, are constantly changing and need to be learned (Wyatt 2010, 2014) (see ► [“Learning”](#) in this book). Organisms can learn signature mixtures through imprinting during a particularly sensitive period of early life (Wyatt 2010) (see ► [“Imprinting”](#) in this book). This learning can allow organisms to recognize their social groups and, consequently, choose a sexual partner that is not related to them and avoid inbreeding or to selectively care for their own offspring, for example (Wyatt 2014).

Signature mixtures of social insects comprise mainly CHCs that, depending on the species, are partly genetically determined and partly influenced by the environment (Wyatt 2010). Distinguishing between signature mixtures (chemical cues) and pheromones (chemical signals) can also be difficult because some hydrocarbons act as pheromones.

Since animals learn and rely on signatures mixtures for their recognition, other animals can likewise exploit them. For example, some animals are able to acquire CHCs similar to those of social insects through diet, contact, or biosynthesis and employ a strategy of chemical mimicry or

chemical camouflage to enter the societies of social insects to exploit them (Akino 2008) (see ► [“Mimicry”](#) and ► [“Camouflage”](#) in this book).

## Conclusion

Chemical cues are present in the environment and used by organisms as sources of information for all aspects of life, thus influencing the behavior of a receiver. Unlike chemical signals, chemical cues did not evolve in the emitter for this function but are used by the organisms that can benefit from them. Chemical signals evolve from chemical cues when they evolve for this function in both the receiver and the emitter. Distinguishing between chemical cues and signals is not always easy because a given chemical may act simultaneously as a signal and as a cue in different organisms.

Many animals can learn their own signature mixtures and recognize members of the same species or colony, as well as sexual partners, and direct their parental care, communication, and other behaviors. Since animals depend on recognition, other animals can acquire their signature mixtures to exploit them.

### Related

Pheromones, Chemical cues, Olfactory cues, Gustatory cues, Kin-recognition, MHC, Arm-pit effect, Self-referent phenotype matching.

### Definition

*Chemical signals* can be defined as messages transmitted through chemosensory modalities (smell and taste) and include things like pheromones, which are secreted chemical signals used to trigger a response in another individual.

This section includes chemical communication with little effort to distinguish between cues and signals. For some, the difference between a cue and a signal relates to intentionality or whether the communication is incidental (Maynard-Smith and Harper 2003). For others, costs and benefits to the sender and the receiver help make the determination between signals and cues, and this is tied closely to evolutionary analysis (Laidre and Johnstone 2013). Therefore, I will review the diversity of messages possible and the unique aspects of gustation and olfaction as communicative modalities. Chemical signals are special in that an animal often gives a small piece of itself in its message. Therefore, this is a communication channel unique for its ability to convey identity.

## Taste and Smell

Chemical signals use the modalities of taste and smell. Often it is difficult to find clear distinctions between the two when it comes to chemical communication as these signals are often combined into an amorphous chemosensory modality. The distinction, however, is important as some animals possess gustation, but not olfaction. The toothed whales, for example, lack olfactory bulbs, yet possess the ability to taste surprisingly well (Cozzi et al. 2016; Nachtigall 1986) despite a reduction in taste receptor genes related to sweet, sour, umami, and bitter sensations in bottlenose dolphins (Feng et al. 2014). As such, we fail to explore one chemosensory modality upon the lack of the other. Furthermore, the tight association between olfaction and gustation causes a lack of clarity as to the role of each in chemical communication. This is seen most strikingly in the flehmen response where animals like giraffes, sheep, cats, and horses will sample urine on their tongues and inhale to provide the vomeronasal organ with stimuli (Mueller-Schwarze 1979). These cues are very important in reproductive assessment (Bland and Jubilan 1987; Swaisgood et al. 2002), but the relative role of gustation versus vomeronasal stimulation remains unknown. Study into the relative

influence of gustation and olfaction might elucidate some of the conflicting results surrounding the taste capacities of anosmic humans (Crosland et al. 1926; Hyman et al. 1979).

## Chemical Signals and Social Recognition

Social recognition is a very important aspect of the natural world. Recognition at the species level (Todrank and Heth 1996) allows for much more successful mating outcomes, as reproductive behavior directed to individuals outside of one's conspecifics rarely results in increased fitness. Repeated, long-term social relationships in animals may facilitate more refined social discriminations either at the kin (Mateo 2003; Todrank et al. 1998) or individual level (Sayigh et al. 1998; Zenuto and Fanjul 2002). Kin recognition without individual specificity exists in many animals as a tool for helping organisms direct kin-selected helping behaviors, avoid inbreeding (Hamilton 1964; Linsenmair 1987) and is often mediated by self-referent phenotype matching (Mateo and Johnston 2000). Colloquially referred to as the "armpit effect," here an organism uses its own odors and the similarities in scent molecules between itself and conspecifics to assess relatedness (Mateo and Johnston 2003). The benefit with such a system is that decisions about who to help and who not to can be made quickly as it does not require previous experience with individuals, a long association or long-term social memory to gauge relatedness (Mateo 2010; Sherman 1977). Conceptually, individual recognition is the most precise social recognition system (Vetter and Caldwell 2015) and the one that is often most difficult to definitively provide evidence for, as one must always be mindful to separate evidence for familiarity from evidence for individual-level knowledge (Tibbetts and Dale 2007). In most mammals, it is the olfactory system that provides the majority of social information (Thom and Hurst 2004) as odor is tied closely to reproductive status, stress (Mackay Sim and Laing 1980), and also relatedness through mediation by the major histocompatibility complex (MHC) (Lawson et al. 2001; Schaefer et al. 2002; Todrank et al. 1998).

No vertebrate has yet been shown to possess pure gustatory social recognition, but the biological blueprint for this capability is present in the mantis shrimp (*Gonodactylidae*). Here highly aggressive individuals use urine to make individual-level distinctions between conspecifics. Species that frequently contact a limited number of individuals over a longer time period are most likely to develop individual-level recognition sometimes as a consequence of aggressive mate-guarding and/or monogamy (Caldwell 1985; Vetter and Caldwell 2015). Shrimp process "taste" using aesthetascs which are unimodal chemosensory sensilla found on their antennules (Mead and Caldwell 2011), but even in this invertebrate species, the socially distinguishing molecules remain unknown (Mead and Caldwell 2011; Vetter and Caldwell 2015). Multichannel variations in individual recognition are present as well, as some closely related species of shrimp, for example, are able to utilize vision, acoustics, and chemical perception together to identify conspecifics down to the individual level (Vetter and Caldwell 2015). Because competitive interactions between these shrimps are usually lethal, it is important to assess whether conspecifics pose an actual threat or possibly present a mating opportunity.

## Chemoreception and Sexual Signals

There is a great deal of variation in chemosensory structures leading to a range of uses for chemicals in sexual signaling. In humans, the olfactory membranes are about the size of two postage stamps, whereas in fair-sized dogs, the same organs would be the size of a pocket handkerchief (Burton 1976). As a result, smell is used in sexual signaling very differently between these two species. Dogs can use smell to determine the presence of prostate cancer in human urine (Cornu et al. 2011), a skill harnessed from an adaptation related to social-sexual identification in their own species (Dunbar 1977). Legendary are the chemoreceptive abilities of moths, capable of detecting a female's sex pheromone 11 km away (see Symonds et al. 2012 for comprehensive

review). Perhaps understudied, however, is the role of eavesdropping by predators and parasites upon these conspicuous chemical signals (Zuk and Kolluru 1998). Parasitic wasps are notorious for their assaults on sexually signaling aphids (Hardie et al. 1991). This eavesdropping phenomena is being explored as a way to mitigate pests in agriculture, by simulating sexual signals (both to catch eavesdroppers and intended targets) and offers a profitable application to the study of chemical signals (Zuk and Kolluru 1998).

## Chemoreception

Stephanie A. Poindexter  
Department of Anthropology, SUNY Buffalo,  
Buffalo, NY, UK

## Synonyms

Gustatory; Olfactory; Sensory Drive

## Introduction

Chemoreception refers to the process in which an organism responds to external chemical stimuli within their environment. In particular, it influences olfaction and gustation, or the sense of smell and taste, respectively. The base mechanism that facilitates chemoreception is the interaction between a chemical stimulus and the outer membrane of a cell. The outer membrane contains protein receptors, and when a particular chemical, which is designed to bind to a specific receptor, is engaged, it initiates a cellular response; a signal travels to the brain or a peripheral neuron (Wyatt 2014). This base mechanism is universal across single and multicellular organisms, though as a result of varying adaptations there is diversity in multicellular organisms' chemoreceptive organs.

## Chemoreceptor Variation

Invertebrate chemoreceptors are contained within hair-like structures and are in variable places, ranging from their antennae to their feet. In vertebrates, the olfactory, vomerolfactory, and gustatory senses are connected to the brain via cranial nerves and interpreted by different regions of the brain. Taste receptors are bundled together to form taste buds that cover the surface of the tongue. The type and number of taste buds vary across taxa and among individuals (Butler and Hodos 2005).

In most tetrapods, the olfactory system is partitioned into the main olfactory system and an accessory system including the vomeronasal organ (VNO). Although there is some overlap between the two systems, it is understood that the VNO is specialized for detection of heavier chemicals, while the main olfactory system is specialized for detection of airborne chemicals (Fortes-Marco et al. 2013). Though the VNO was initially hypothesized to function solely in detecting pheromones, current research does not support this, as the VNO can also detect non-pheromone chemicals.

The VNO in amphibians and reptiles is connected to their mouth. Snakes and some lizards collect cues by tongue-flicking. Some ungulates and felids collect urine-borne pheromones on their tongues through licking and lip-curling. Though there is an on-going debate as to whether humans have a functional vomeronasal system (Hohenbrink et al. 2012), olfaction plays a significant role in how animals including humans, engage with conspecifics, other organisms, and the environment. There are many contexts where the sense of smell is used including foraging, mate selection, risk identification, and long-distance travel.

## External Cues

Among volatile odorants derived from various animals, insects, plants, and microorganisms in the external world, the odorants that are beneficial only to perceivers and not to the emitter are called kairomones. Conversely, odorants that are advantageous only to issuers, such as antifeedant volatiles from plants, are called allomones. Odorants that benefit both the perceiver and emitter are called synomones. Together, all three classes of odorants kairomones, allomones, and synomones are called allelochemicals (Wyatt 2003).

The sensory drive hypothesis proposes that evolution influences signal production and signal detection in a dynamic world and predicts that selection favors mechanisms that facilitate communication depending on the environmental

background (Endler 1992). Chemical signals and cues must reach the recipient; then the recipient must be able to detect the intended cue to respond appropriately. Chemical signals must travel through varying abiotic conditions such as wind and humidity. Chemoreception plays a vital role in how organisms engage with the world around them.

## Chemotaxis

Divya Singh<sup>1</sup>, Anuj Kumar Singh<sup>2</sup> and Paushali Ghosh<sup>1</sup>

<sup>1</sup>School of Biotechnology, Institute of Science, Banaras Hindu University, Varanasi, UP, India

<sup>2</sup>Department of Skin and Venereal disease, LLRM Medical College, Meerut, India

### Definition

The term “chemotaxis” has been derived from two words – “chemo” meaning chemical and “taxis” meaning movement. Thus, it can be defined as the directed movement of a cell or an organism in response to chemical stimulus (Willard and Devreotes 2006).

### Introduction

Chemotaxis is one of the most important phenomena occurring commonly in the living beings. It is exhibited by a variety of organisms ranging from unicellular to multicellular. In unicellular organisms like amoebae and bacteria, chemotaxis is primarily adopted as foraging machinery (Willard and Devreotes 2006). However, in multicellular organisms, it plays an essential role in wound healing and inflammatory responses as well as in cell migration during development (de Oliveira et al. 2016). In addition to this, it is major contributing factor in the metastasis of cancer cells. Chemotaxis can either be positive or negative depending on the direction of motion of the cell in response to the chemical signals. If the cell moves towards the direction of the signal, it is termed as positive chemotaxis and the chemical signal is then considered as chemoattractant. But if the cell moves against the direction of the signal, it is known as negative chemotaxis and the chemical signal in such case is regarded as chemorepellent.

## Chemotaxis in Prokaryotes

In general, flagellated bacteria use the process of chemotaxis for locomotion purpose. It involves a series of dispersed run and tumble movement guided by chemical stimulus which ultimately helps the bacteria in reaching favorable environment (such as food) and avoiding unfavorable conditions (such as toxins). Berg and Brown (1972) have extensively studied the basic mechanism underlying this behavior in *Escherichia coli* which is as follows:

- (i) Specific chemoreceptors located on the surface of bacterial membrane sense and bind chemical cues (ligands).
- (ii) Binding of ligand to chemoreceptor activates the two-component signaling pathway (when repellents are present or attractants are absent) across the cell membrane leading to the autophosphorylation of CheA, a protein histidine kinase. This in turn, results in the increased phosphorylation of CheY (a response regulator).
- (iii) Phosphorylated CheY diffuses freely through the cell and binds to FliM (a flagellar protein) when it comes into contact with the flagellar motor.
- (iv) Then phosphorylated CheY-FliM complex shifts the orientation of flagellar rotation from counterclockwise to clockwise direction, thereby inducing tumbling movement. Thus it can be inferred that clockwise rotation promotes tumble whereas counterclockwise rotation promotes run.

## Chemotaxis in Eukaryotes

The process of chemotaxis in eukaryotes is quite different from that of prokaryotes. Prokaryotes being smaller in size cannot directly sense concentration gradient. They detect their surrounding temporally and swim continuously by redirecting themselves every time they perceive alteration in the gradient. In contrast to this, eukaryotic chemotaxis comprises of spatially detecting

concentration gradient through asymmetric activation of receptors known as G protein-coupled receptors (GPCRs). GPCRs are present uniformly throughout the cell surface which binds specific chemoattractants and generate signal that controls movement (Levine and Rappel 2013). GPCRs signaling are involved in the deployment of immune cells such as neutrophils, monocytes, macrophages, etc. at the site of infection and tissue injury in mammals. In addition to the immune cells, a large group of cells namely, mast cell, fibroblast, endothelial cells under certain physiological conditions are considered to show motility because of GPCRs signaling (Kedrin et al. 2007).

Furthermore, GPCRs signaling assists social amoeba *Dictyostelium discoideum* in their foraging mechanism by mediating chemotactic responses. Besides this, GPCRs are also associated with the starvation response in *Dictyostelium discoideum*. During starvation, distinct amoeba form aggregates. This process of aggregation is governed by gradients of cAMP and is followed by a series of morphogenetic transformation and cell fate selection which leads to the formation of multicellular structures enclosing spores that can withstand starvation (Willard and Devreotes 2006). Several studies conducted on G proteins have not only proved its role as “molecular switches” but also demonstrated how GPCRs signaling functions in relation to chemotactic signaling and regulate directional movement by deciphering the direction of external concentration gradients (Franca-koh et al. 2010).

## Conclusion

Chemotaxis can be regarded as a fundamental sensory process. Its role in prokaryotes is quite similar to the decision-making capabilities of higher living organisms having brains for processing sensory information. However, in eukaryotes, G proteins have an indispensable role in regulating signaling pathways in response to chemotactic ligands under controlled space and time. In addition to this, there are different chemotactic receptors which exhibit diverse type of specialized mechanisms to bind the ligands

and subsequent activation of downstream proteins via transmembrane signaling. Recent advancements have been made in understanding the molecular mechanism that regulates transmembrane signaling. Although, a deep understanding of how these signaling pathways interact with each other is still required to develop new models.

## Definition

The coordinated incursion of a coalition of adult chimpanzees into the territory of an adversary chimpanzee community that often leads to either the displacement or elimination of the rival group's members.

## Introduction

Phylogenetic comparative studies have identified that conspecific killings are widespread across nonhuman taxa. Gómez et al. (2016) estimated the level of lethal aggression in 137 families involving 1024 mammalian species. In contrast

to within-group attacks, intergroup killings were found in substantially fewer taxa. To date, reports of lethal between-group interactions (Gómez et al. 2016; Wrangham 1999) can be found in grey wolves (*Canis lupus lupus*), lions (*Panthera leo*), spotted hyenas (*Crocuta crocuta*), and cheetahs (*Acinonyx jubatus*). Additionally, some non-human primates, including spider monkeys (*Ateles belzebuth*) and mountain gorillas (*Gorilla beringei beringei*), have exhibited related behaviors. Moreover, lethal intergroup conflict has been studied in great detail in chimpanzee (*Pan troglodytes*) communities. Observations and analyses of violent interactions between chimpanzee groups have been scientifically received with varying levels of acceptance due to the potential implications of such findings. The current entry covers fundamental hypotheses and related empirical studies that have attempted to characterize this behavioral phenomenon.

## Evidence of Chimpanzee Intercommunity Killings

Jane Goodall's primatological observations challenged the notion that only state-level human societies engage in lethal intergroup conflict. Early in her study of chimpanzees in Tanzania, Goodall established a feeding location near her research station to normalize her presence within their ecology through habituation. Subsequently, she identified two chimpanzee subgroups, northern and southern, based on the routes that individuals took after feeding at the camp. Initially, Goodall considered these parties to be entirely independent of each other; however, closer inspection revealed that both northern and southern chimpanzees were once part of the same community. By 1973, she had officially named both groups based on their physical proximity to geographical landmarks. The northern community, named Kasekela, occupied the area between the Katombe and Kasekela valleys. The southern group occupied the Kahama valley and was named accordingly. Despite their common origin, interactions between Kahama and Kasekela chimpanzees ranged from avoidance to open hostility (Goodall 1986). Five years after its detection,

intense intercommunity clashes reduced the southern Kahama's range from 10 km<sup>2</sup> to less than 2 km<sup>2</sup>. Any remaining females went on to join rival groups, evidencing the end of the Kahama community. Their elimination allowed Kasekela to expand its range to 17 km<sup>2</sup>. Although during this period, Kasekela experienced a considerable expansion in its community range area, their growth eventually halted. Since Kahama's territory previously acted as a barrier between Kasekela and other southern factions (such as Kalande; Goodall 1986), the northern community experienced a series of raids leading to its territorial reduction. Intercommunity aggression at Gombe also had substantial demographic effects. Williams et al. (2008) estimated that half of the 12 male Kahama and Kasekela deaths between 20 and 30 years of age were the product of intercommunity conflict (taking both suspected and observed cases).

Even though some researchers initially received Goodall's reports from Gombe with skepticism, independent evidence would support her observations of lethal agonistic interactions between chimpanzee groups. Nishida et al. (1985), for instance, reported similar findings from the Mahale Mountains in Tanzania. Initially, two communities, named K-group and M-group, occupied neighboring territories. In less than 20 years, K-group experienced a demographic collapse. This process began with the systematic disappearance of most of its adult males. By 1983, only one adolescent male and three females remained. Nishida and colleagues, however, did not observe M-group coalitions killing K-group males. Later, based on circumstantial evidence, the authors estimated that approximately 4% of the K-group's deaths could have been the outcome of intercommunity aggression (Nishida et al. 2003). The authors noticed that as the number of adult males' decreased, female dispersal increased, concluding that demographic changes encouraged cycling females to affiliate with M-group males (Nishida et al. 1985).

Recently, Nakamura and Itoh (2020) revisited the demographic patterns reported from K-group and M-group to determine whether it was unusual for communities to lose six males in 20 years or

less. The authors found that a higher number of M-group males died or disappeared relative to those of K-group, dispelling Nishida's original claim that the loss of K-group males evidenced an abnormal demographic change. The main difference between the communities instead rested on the number of adolescent males reaching adulthood. Even though Nakamura and Itoh included other potential causes underlying the loss of K-group males, such as old age, disease, and injury, according to the authors, these factors could only have weakened the community and facilitated M-group raids, not been a sole cause of demographic shifts.

In addition to Mahale, observations conducted at Kibale National Park, Uganda, counter the claim that intercommunity killings are exclusively the product of anthropogenic factors, such as food provisioning, and instead of adaptive behavior (Watts et al. 2006). Mitani et al. (2010) analyzed patrol data collected from the Ngogo chimpanzee community at Kibale. In ten years, Ngogo coalitions eliminated 18 (21 if adding inferred cases) foreign rivals. Over 90% of the killings occurred during Ngogo patrols, whereby coalitions of individuals, mostly comprised of males, traveled beyond the community's border, generally in a single file formation, in search of rival groups (feeding and socializing decreases during such patrols). Over 60% of the killings transpired near Ngogo's northeastern border.

Because the authors lacked the exact number of individuals inhabiting the targeted community, Mitani et al. (2010) employed a series of heuristics to calculate the killing rate in that northeastern region. Imputing an average of 47 individuals from 8 different chimpanzee communities, the researchers calculated a rate of 2790 chimpanzees killed per 100,000 per year. Alternatively, if instead assuming that the Ngogo and northeastern communities had an equivalent group size of 150 individuals, the rate decreases to 867 killed per 100,000 per year. Mitani et al. predicted that the estimates from Kibale were considerably higher, relative to those computed for nine other chimpanzee communities spread throughout Africa, partially because patrolling occurs more

frequently at Ngogo (Mitani and Watts 2005a; Watts and Mitani 2001; Watts et al. 2006).

The elimination of foreign rivals led to Ngogo's territorial expansion. Mitani et al. (2010) observed an increase in the amount of time Ngogo chimpanzees socialized, traveled, and foraged in annexed regions. Additionally, in a previous publication, Mitani and Watts (2005a) considered the ecological and evolutionary correlates of chimpanzee patrolling events at Ngogo. The study considered the size of male patrol groups, the availability of fruit, the presence of estrus females, hunting episodes, and the presence of intruders. A logistic regression model determined that only male party size and fruit availability significantly predicted patrolling events. Consistent with previous studies (e.g., Mitani and Watts 2005b), these two variables were correlated. Additionally, a model limited to those latter two predictors determined that only male party size had a significant contribution to the model.

Similarly, Wilson et al. (2012) analyzed behavioral and ecological data from the Kanyawara chimpanzees inhabiting Kibale National Park. The study considered associations between the number of adult males, the number of estrous females, the number of infants, the distance between an encounter's location and the center of the territory, as well as the percentage of fruit consumption (disaggregated into different fruit species) on 120 intercommunity encounters. The analysis revealed that in over 80% of the cases, individuals limited their agonistic interactions to vocal displays. Additionally, over 60% of these interactions transpired close to Kanyawara's southeastern boundaries (Wilson et al. 2012). The authors found that fruit consumption, particularly that of *Uvariopsis congensis*, as well as the average number of adult males in a patrol party, positively and significantly predicted the distance traveled from the center of the territory to the location of an encounter.

The literature reports noticeable differences in the frequency and intensity of between-group conflicts among chimpanzee field sites. Boesch and collaborators (2008), found that, in contrast to Budongo (Reynolds 2005), Gombe (Goodall

1986), Ngogo (Watts et al. 2006), Kanyawara (Wrangham et al. 2006), Mahale (Nishida et al. 1985), and Loango (Boesch et al. 2007), Taï chimpanzee communities exhibited lower death rates due to intergroup aggression (Northern Group = 0.00; Middle Group = 0.00; and Southern Group = 0.27). Boesch and colleagues attributed this difference to the nearby presence of in-group members ready to aid potential victims of intercommunity aggression. For instance, the authors described that in over 25% of all visual contacts, individuals provided support to in-group targets. Moreover, in all observed instances of adult female sequestration (foreign males corraling the victim, hindering her from returning to her community), supporters assisted the target and facilitated her escape (Boesch et al. 2008). In contrast to this pattern, at the time of the latter publication, only four cases of support in other chimpanzee communities had been observed, three at Ngogo, and one at Kanyawara.

### Empirical Examinations of Anthropogenic and Adaptive Hypotheses

Despite the evidence gathered over the years, some academics remained unconvinced with evolutionary and adaptive explanations of this phenomenon. Instead, those authors claim that anthropogenic pressures better fit the data. In a thorough examination, Wilson and collaborators (2014) summarized the various points raised by critical authors over the years. For Wilson, the human impact hypothesis predicts the following behavioral patterns: (a) chimpanzees and bonobos should exhibit similar killing rates; (b) the killing rate should display a positive trend over time; (c) males and females are equally expected to be the perpetrators and victims of these attacks; (d) the age of individuals should not influence the probability of becoming a victim; (e) genetic relatedness between attackers and victims should not predict killings; and (f) there should not be any numerical asymmetries between perpetrators and victims during attacks. Contrarily, the adaptive strategies hypothesis predicts the following:

(a) chimpanzees should exhibit higher killing rates than bonobos; (b) killing rates should not increase over time; (c) males should be the main perpetrators and victims of lethal competition; (d) infants close to their mothers should be especially vulnerable to these attacks; (e) attackers should target genetically unrelated individuals in rival communities; and (f) killings should occur more often when prospective attackers outnumber their victims.

Wilson et al. (2014) compiled data from four bonobo communities and 18 chimpanzee communities (Eastern = 12; Western = 6), studied for over 50 years. The database contained information on 152 instances of lethal aggression, including 58 observed, 53 suspected, and 41 inferred killings. The authors also gathered information on: (a) whether or not researchers used provisioning as part of the habituation process; (b) the size of the protected area (in km<sup>2</sup>); (c) the intensity of human disturbance; (d) the geographical location of the chimpanzee community (eastern or western); (e) the mean number of adult males per community; and (f) the mean population density per community. The first three indicators are directly related to the human impact hypothesis, whereas the remaining three are associated with the adaptive strategies hypothesis. The authors employed a series of Poisson regressions, controlling for observation time. Wilson et al. (2014) also calculated fit indicators (QAICc), along with their respective  $\Delta$ QAICc and weights, to adequately compare the competing models. Their analyses revealed that chimpanzees had higher killing rates relative to bonobos. The model containing the dimension of the protected area, the severity of human disturbance, and the occurrence of food provisioning received little support ( $\Delta$ QAICc = 3.8; weight = 0.06). All three predictors had negative associations with killings. The best model included the mean number of adult males per community and the population density per community ( $\Delta$ QAICc = 0.00; weight = 0.40). Overall, the ratio between QAICc weights suggests the adaptive strategies hypothesis is 6.8 times more supported than the human impact hypothesis.

When looking at the identity of the attackers and their targets, males were found to participate

in over 90% of the killings. Moreover, the study detected significant sex differences after controlling for observation time, wherein, relative to females, males were more likely to kill a conspecific. Females would attack only adult rivals and participate only when part of a male-led coalition (Wilson et al. 2014). In the case of the victims, infants and adult males were usually targeted. In the majority of cases, the attackers and their targets inhabited different communities and were therefore genetically distant (Wilson et al. 2014). Targets could however include mothers with offspring or solitary victims. The authors estimated that a median of nine males per party was required to outnumber the victims. Wilson and colleagues also estimated the proportion of attackers relative to targets. Raiders outnumbered targets 8:1 (analysis restricted to 30 cases featuring data on party size).

### Power Imbalances and Numerical Assessment

The imbalance-of-power hypothesis provides an adaptive framework through which one can explain coalitional, between-group, killings in chimpanzees (Wrangham 1999). It was formally introduced by Richard Wrangham and colleagues but is traceable to Jane Goodall. The hypothesis claims that lethal violence intrinsic to raiding can provide a selective advantage to aggressing societies in nonlethal contexts, such as the accumulation of resources. This process occurs through a balancing of the costs and benefits of individual raids. Since the associated behaviors involve guaranteed costs, such as time and energy spent patrolling, and potential costs, such as injury or death, attacks are carried out strategically to be most worthwhile to the broader society (Manson et al. 1991; Wilson 2013; Wrangham 1999). The key variables relevant to action are the size and constitution of parties when they detect one another. The larger an opposing party, the less likely another party is to attack, and by extension, the more likely they are to be attacked. Thus, if a patrolling group of males finds a single member of a neighboring society without nearby defenses,

the likelihood of severe injury or death to group members during an attack is quite low. Meanwhile, the neighboring society, which may compete for resources or mates, experiences a slight competitive disadvantage from the loss.

Wilson et al. (2001) played a previously recorded “pant-hoot” from an unknown male to parties composed of anywhere from zero to nine adult males. Pant-hoots are a common form of chimpanzee communication, audible up to two kilometers away and utilized to signal anything from newly discovered food to violent conflict. Multiple variables were measured to investigate underlying influences on response patterns and possible differences based on group composition. Included were the location and proximity to society borders (both those of the loudspeaker and the party), number of individuals by approximate age and sex, and individual agonistic rank (Wilson et al. 2001). The only variable that significantly predicted both a vocalization response and a physical approach was the number of defending members in a group. This provided strong preliminary support for the claim that chimpanzees possess the ability to determine their likelihood of success in performing a raid through knowledge of their group’s strength and an auditory understanding of that of their opponents.

Another study, this one ethological, at Kanywara, contributed further to answering these questions (Wilson et al. 2002). Over 15 years, Wilson and colleagues collected data on multiple parties, from their composition, which included counts of infants, adult males, and females in estrus, to their proximity from societal borders, and even the value of food resources based on category and proximity to the center of the range. Food resource valuations were based on the amount of time individuals spent foraging in the proximity of a resource disputed by members of multiple societies. Although most interactions between members of opposing groups occurred from a distance greater than one hundred meters apart and remained nonphysical, the number of males in each party was once again the only variable to significantly predict the approach. Those with a sufficient numerical asymmetry, previously determined to be any group with 1.5, or more,

times as many adult males as the opposition, were likely to approach (Wilson et al. 2002).

In summary, chimpanzee societies must respond to ecological pressures, such as continuous scramble competition for ripe fruit, by leveraging their opportunities to disadvantage nearby rivals physically. The relative fitness of neighboring societies appears to depend heavily on their dominance over one another in capturing and maintaining an adequate supply of food and mating-based resources. These crucial and ever-fluctuating markers of between-group dominance encourage the selective killing of valuable members of competing societies when the costs render such behaviors to be actionable and reasonably safe, within the thresholds discussed above. Though many factors impact vulnerability to attack, the likelihood of action still appears to be based solely on the numerical asymmetry between parties. The imbalance-of-power hypothesis nests these individual asymmetries of conflict within broader societal continua, relevant to the overall fitness, and demographic well-being, of competing societies in a given population.

### Intercommunity Conflict and Fitness Outcomes

According to Wilson (2013), as well as Wilson and Wrangham (2003), scientific explanations often consider one or more of the following potential benefits obtainable through violent intergroup conflict: (a) gaining access to feeding grounds; (b) recruiting foreign females; (c) decreasing the risk of becoming a target of intergroup aggression; (d) reducing the probability of foreign males copulating with native females; and (e) eliminating sexual rivals.

Empirical evidence supports some of these predictions. For example, Williams and collaborators (2004) analyzed behavioral and ecological data collected on Gombe chimpanzees over 18 years. The study explored the direct and indirect associations of community range size with both chimpanzee social interactions and life history indicators. Even though the authors did not find a significant association between a broader range

and the total number of females, additional models detected that range size positively predicted the amount of time that individuals allocated to foraging in larger feeding parties, as well as a frequency of contact between males and sexually receptive females. A larger community range size also negatively predicted female interbirth intervals, suggesting that access to resources, in this case as a product of area expansion, has a direct effect on reproductive output. Researchers have also found that a larger range and a lower population density are associated with heavier body mass (Pusey et al. 2005).

Other perspectives have also considered the influence of contextual factors. According to the *group augmentation hypothesis* (Langergraber et al. 2017), individuals are willing to accrue a personal cost and not obtain an immediate benefit by participating in patrol parties, as long as that contribution facilitates the group in increasing its size and leads to greater reproductive success. Langergraber et al. (2017) analyzed behavioral, kinship, and genetic data collected from male chimpanzees inhabiting the Ngogo community at Kibale, Uganda. A generalized linear mixed model identified that male paternity success, along with male rank in the dominance hierarchy, positively predicted patrol participation. Other indicators, such as the number of maternal kin in the group or male age, did not reach statistical significance. Langergraber et al. analyzed the paternities of 11 adult males. The authors calculated that males, based on over 110 births, sired on average 3.3 offspring. The data revealed that all males participated in patrols, even if they did not have offspring at the time. Only 36% of all adult males did not reproduce. These results indicate that, although adult males do not obtain a direct fitness benefit from patrolling, indirectly, their probability of successfully reproducing increases as an outcome of the group's expansion. Contrary to other publications, the analyses also identified a negative association between the number of males in the group and males' participation in border patrols, suggesting a rise in social defection as the number of participants increased.

Past research at Kibale has also found male dominance rank to be independent of patrol frequency (Watts and Mitani 2001). In contrast,

patrolling behavior was shown to have a positive and significant association with the mean percentage of copulations (this association became non-significant after controlling for the individual's dominance rank; Watts and Mitani 2001). Additional analyses concluded that even though the proportions of patrolling behavior (the number of times a male participated in a patrol, given the number of opportunities the individual had to join a patrol party) did not predict male mating success, controlling for the individual's rank had a positive relation with the criterion variable (Watts and Mitani 2001).

In addition to the group augmentation hypothesis, other views have also considered the role of the group characteristics on conflict. According to the intergroup dominance hypothesis, all individuals in the community benefit from expanding the territory, for instance in obtaining access to feeding grounds, and in the case of males, the ability to recruit more females (Crofoot and Wrangham 2010). Some evidence supports this perspective. Lemoine and colleagues (2020b) examined demographic and behavioral data from four chimpanzee groups over 54 years of observation in Taï National Park, Ivory Coast. The authors developed a neighbor pressure index, comprised of the frequency of intergroup interactions, the value of the location according to its yearly usage, and the relative physical distance between the location where the interaction occurred and the center of the territory's center. Lemoine et al. (2020b) also considered the number of adult males per group as a potential proxy for intergroup competition. Additionally, the study considered the number of weaned individuals as an indicator of intragroup competition. The analyses revealed that exposure to intense neighbor pressure during pregnancy had a negative association with prenatal offspring survival. This pattern, however, did not generalize to postnatal infant survival. In a subsequent analysis, the authors computed a Linear Mixed Model estimating the association between the mean number of adult males, the neighbor index, and the mean number of wean individuals, with female interbirth intervals (IBI's). As predicted, both the neighbor index and the number of wean individuals increased female IBI's, whereas the number

of adult males had a significantly negative relation on IBI's.

Lemoine et al. (2020a) explored, in a later publication, the link between group dominance, territory size, and neighbor pressure. Their study found that group size had a positive and significant relation with the size of the territory. Likewise, larger groups scored lower on the neighbor pressure index. Model comparison determined that the total number of individuals, rather than the number of adult males, better predicted the criterion variables. The results from these studies suggest that neighbor pressure and territorial expansion could mediate the association between group size and reproductive outcomes.

### Intergroup Killings in Chimpanzee and Human Societies

Due to their phylogenetic proximity, studies exploring the ecological and evolutionary correlates of chimpanzee intercommunity conflict could provide researchers with a deeper understanding of human between-group aggression (Glowacki et al. 2020; Wrangham and Glowacki 2012; Wilson and Glowacki 2017). Wrangham et al. (2006) gathered data on human and chimpanzee lethal aggression. The database included information on nine chimpanzee communities, observed over the course of 158 data-years. During this period, the authors counted at least 49 observed and 27 suspected instances of intercommunity killings. Aggregating these instances across all communities generated a mortality rate of approximately 125–306 deaths per 100,000 individuals per year (Wrangham et al. 2006). The authors also gathered information on intergroup mortality rates in small-scale human societies. The median mortality rate from intergroup aggression in these human societies varied depending on the type of subsistence economy (Hunters:  $n = 12$ , median = 164, per 100,000 per year; Farmers:  $n = 20$ , median = 595, per 100,000 per year). Significance tests identified that farmers had higher mortality rates relative to hunters (Wrangham et al. 2006). The killing rates of chimpanzees and hunter-gatherer societies thus exhibited a considerable overlap. The authors,

however, noticed a slight difference between the groups. Whereas in chimpanzee communities, infants, adolescents, and adult males were generally the victims, in human groups, adult males were usually the only targets of these attacks.

### Discussion

Although lethal aggression is a widespread phenomenon across human and nonhuman taxa, intergroup killings occur in a small subset of species. Although primatologists have described between-group attacks in nonhuman primates (Crofoot and Wrangham 2010), most of the literature on this subject concerns intercommunity killings in chimpanzees. Initially, reports of intergroup attacks in Gombe and Mahale were met with considerable skepticism. Critics claimed that anthropogenic factors, including the use of food provisioning as part of the habituation process, artificially increased the frequency and intensity of conflict between communities. Observations of intergroup lethal attacks in non-provisioned field sites countered these claims. Skeptics also contended that habitat destruction and human encroachment better explained chimpanzee territoriality and lethal coalitional aggression. Recently, however, cross-community comparisons exploring the influence of food provisioning, degree of human disturbance, territory size, population density, the mean number of males, and location, concluded that the anthropogenic variables do not adequately predict intercommunity killings. Thus, adaptive hypotheses currently provide the most explanatory depth for these behaviors and therefore find themselves best supported within the relevant literature.

## Definition

Chondrichthyes' communication is the exchange of information and social behavior, both intraspecific and interspecific, between a sender and a receiver, and at least one of these is a chondrichthyan.

## Introduction

Chondrichthyes belong to one of the oldest and most diverse vertebrate groups (entry ► [“Vertebrates \(Chordata\)”](#)). Featured by two synapomorphic characteristics, a cartilaginous skeleton superficially mineralized by prismatic calcifications and the presence of claspers (evolutionary distinct than any similar structure in other clades, derived from pelvic-fin modifications) in male representatives for internal reproduction, the group is recognized for its evolutionary success involving historical persistence, having survived several events of mass extinctions over the past 400 million years (Carrier et al. 2012). The extant diversity of the group, with 1282 valid species (Fricke et al. 2021), can be divided into 2 branches: the Elasmobranchii (sharks and rays) and the Holocephali (chimeras and their relatives).

Representatives of this group can navigate thousands of kilometers to mate, prey, lay eggs, and other reasons. Some mechanisms by which chondrichthyan species can perceive their environment and navigate by it include mechanoreception (mainly auditory and lateral line systems), electroreception, chemoreception, and vision (entries ► [“Chondrichthyes Locomotion”](#), ► [“Chondrichthyes Navigation”](#), and ► [“Chondrichthyes Sensory Systems”](#)). In addition, the senses listed previously also aid in the communication present in the group, as presented below.

The definition of animal communication is somewhat troublesome since there is no consensus in the literature (for a review, see ► [“Communication”](#)). However, some elements that usually define it are the existence of a **sender** and a **receiver**; the presence of an emitted **signal**; and the **communication** between parties, enabled by such signals. In general, animals communicate using visual, acoustic, chemical (including olfactory), tactile, and electrical signals, and all these modes are present in Chondrichthyes.

In Chondrichthyes, communication is essential for several of their behavioral patterns. For example, some species have their survival enhanced by presenting certain luminescence patterns,

functioning as backlighting to avoid predators and attract prey. Behaviors involving communication, mainly sensory-induced behaviors, function as mediators of rheotaxis (orientation to water currents), detection of prey, prevention of predators, and hydrodynamic imaging to locate objects (Carrier et al. 2012). Furthermore, social communication and schooling are also major behaviors of the group.

Most of the published data on Chondrichthyes communication is reported for elasmobranchs. However, we will also present chimeroid communication, whenever information is available in the literature. This entry will focus on chondrichthyans' communication modes, being divided according to subsequent classifications and their specification: (1) **visual** (eyesight, agonistic and reproductive postures, type of swim, patterns, colors, and light emission), (2) **acoustic and mechanoreception** (hearing and other mechanosensory receptors), (3) **chemical** (flair and pheromone), (4) **tactile** (recognition bite, feeding frenzy, and mating), and (5) **electrical** (electroreception). Finally, behavioral studies are reasonably scarce for chondrichthyans, so that morphological (entry ► "[Chondrichthyes Morphology](#)") and physiological studies are the main sources of information about their ecological aspects that are difficult to observe in the wild.

## Visual Communication

Chondrichthyes' visual communication is not highly discussed in the literature. Despite a somewhat large body of evidence that chondrichthyans have well-developed visual systems (see Hart et al. 2006 for a revision), there is little information on the role of vision in their everyday life and which visual targets provoke behavioral responses. Here, we will focus on aspects of visual communication, signal, and meaning that can be found in the literature.

Several anatomical features indicate aspects of visual behavior and communication patterns. For example, chimeras, usually deep-sea fishes, frequently have prominent eyes, and, as the size of an animal's eyes influences its visual capabilities,

several works suggest vision may be particularly important for those fishes (Lisney 2010). Most chimeras have a pure rod retina, which allows them to notice the presence of predators and prey once the individual enters their visual field, even in zones with low sunlight levels (Bozzano and Collin 2000). Furthermore, the *tapetum lucidum*, a structure present in chondrichthyans (as well as in several other vertebrates), reflects the light that has passed through the photoreceptors back to them, improving visual accuracy in darker environments and being a primary mechanism to enhance visual sensitivity. Comparing two species of chimeras from different depth intervals, interspecific differences in the aspects of the *tapetum* indicate the species that occupy deeper waters might have higher light sensitivity than the species closer to the surface (Maddock and Nicol 1978).

In contrast, elasmobranchs present a variety of retinal configurations, from pure rod to rods and cones. Cones are most abundant in the retinal configurations of predominantly shallow-dwelling, diurnally active species, and multiple cone types suggest some elasmobranchs have the potential for color vision (Hart et al. 2006). Even though several freshwater lineages exist, most elasmobranchs occupy marine environments, whose tridimensional structuration is variable, and the role of vision for environment perception and communication might correlate to the species lifestyle (occupying coastal or open ocean areas, depth at the water column, and so on). Furthermore, the quality of vision in these animals depends not only on anatomical factors but also on ecological factors that affect their visual sensitivity and communication, acting as a receiver or a sender. Nevertheless, visual signals dictate visual behaviors within the group, mainly involving reproduction, aggression, and predation (Lisney et al. 2012).

## Agonistic Postures

A very common class of behavior among animals is agonism, which occurs in different competitive contexts and is important for the social dynamics and evolutionary aptitude of many animals. For example, individuals that are defeated or displaced during agonistic behaviors (interspecific or

intraspecific competitions) most often disperse to suboptimal environments, causing a reduction in their food and reproductive capacity (Reese 1978).

The agonistic display is best known in the gray reef shark (*Carcharhinus amblyrhynchos*) that features a “hunch display” in which the snout is lifted, and the back is arched. This stance occurs in response to persecution or possible agglomeration caused by divers or other animals (Johnson and Nelson 1973). There are four postural elements of this display: (1) snout raised, (2) pectoral fins depressed bilaterally and to the same angle, (3) arched back, and (4) lateral flexion of the body. Besides, these postures are combined with two locomotive elements: (1) side swimming and (2) rolling and/or looping, spiral swimming (Johnson and Nelson 1973). All these postures can occur when the animal feels threatened (Hart et al. 2006) and increase in intensity according to the signal emitted by the sender, as well as to the degree of restriction of the escape route (Johnson and Nelson 1973). Also, if the signal persists, the hunch display may turn into a withdrawal strike or a quick, open-mouthed slashing attack (Johnson and Nelson 1973). This “hunch display” may occur both as an interspecific behavior likewise against conspecifics (Myrberg and Gruber 1974).

Another agonistic behavior presented by the white sharks (*Carcharodon carcharias*) is the great “tail slap” on the water surface, a representation with visual and acoustic components used to keep competitors away, whether they are from the same species or not (Klimley et al. 1996). The intensity and frequency of such signals can transmit information about the relative strength of the sender, indicating its fighting quality to the receiver.

### Reproductive Postures

Characterized by internal fertilization, the patterns of reproduction and development in Chondrichthyes are diverse, but very little is known about their reproductive behavior. Mating observations are generally made in captivity, with few observations in the natural environment. Some copulatory behaviors were observed involving partner recognition and

courtship in elasmobranchs, with the female usually initiating the court (Hart et al. 2006).

Copulatory cues mainly use pheromones combined with visual displays, such as the arching of the female’s back, an inclination as a form of “submission,” and dilation of the cloaca, signaling receptivity to the male (Pratt and Carrier 2001). However, male gray nurse sharks (*Carcharias taurus*) usually initiate the mating behavior, expressing increasing aggression and displaying clasper flexion (Gordon 1993).

### Patterns and Colors

Despite elasmobranchs generally having neutral colors to the human eye (when compared to the bright colors seen in many other fishes), non-subjective spectroradiometric color measurements indicate most elasmobranchs present some degree of countershading that tends to be more apparent in active pelagic sharks, besides benthic and deepwater sharks (Hart et al. 2006). The markings’ shape and color notably contrast against the background and may work as camouflage, crypsis, or disruptive coloring. There is evidence that female nurse sharks (*Ginglymostoma cirratum*) appear to select larger and darker males, suggesting that coloration could be also used in intraspecific communication for partner selection (Pratt and Carrier 2001).

### Light Emission

Literature shows us that, more than anything else, the ability to see probably shaped the evolution of vision in fishes as a way of avoiding obstacles and finding shelter, besides recognizing prey and predators (Paitio et al. 2016). However, for all these behaviors to effectively occur, the presence of light in the environment is a central component, and light is scant in deep environments. Even though sunlight does not naturally reach deep waters, these are not devoid of light (from the perspective of nonhuman animals) due to two distinct phenomena of light emission by several organisms: bioluminescence and biofluorescence.

Bioluminescence is the ability of a living organism to produce, through chemical reactions, and emit visible light, being reported for 46 fish families so far (Paitio et al. 2016). Among

elasmobranchs, bioluminescence is present in, at least, three Squaliformes families (Etmopteridae, Dalatiidae, and Somniosidae) (Duchatelet et al. 2021), and it seems to be nonexistent or has not been yet confirmed in rays, skates, and Holocephali (Paitio et al. 2016).

The light organs can perform several functions, and their locations are somewhat associated with the functions of the emitted light (Paitio et al. 2016). This light can be used by the sender for intraspecific communication, recognition, schooling, and mating. In the case of interspecific relationships, luminescence also plays a role in prey and predator detection. To avoid predators, back-lighting is particularly used, a method called counter-illumination: the species emits light in the ventral body region, matching the light from above, confusing the predator, and camouflaging itself. In bioluminescent sharks, numerous small light organs are predominantly present in the ventral region of the body, but lower densities can even reach the dorsal areas in dalatiid species (Paitio et al. 2016).

Different from bioluminescence, biofluorescence is the phenomenon where the organism absorbs low wavelength (deep blue) from the environment and emits high wavelength (green) light. To date, there are only five known elasmobranchs with this feature: one stingray (family Urotrygonidae), one wobbegong (Orectolobidae), and three catsharks (Scyliorhinidae). Given that these families are not evolutionary closely related, biofluorescence seems to have evolved at least three independent times within Chondrichthyes. Thus far, no specimen of Holocephali has been shown to be biofluorescent (Gruber et al. 2016).

In a Scyliorhinidae species, *Cephaloscyllium ventriosum*, light emission is possibly a sexually dimorphic feature, with females presenting more body regions able to emit light, and males with claspers greatly fluorescent. These elasmobranchs are not only able to emit but also to perceive the high wavelength light emitted by conspecific others, in clear visual communication. However, because predators might not be adapted to see this light, these animals become invisible to those who lack a similar visual capability in a dark environment (Gruber et al. 2016).

## Mechanoreception and Communication

The propagation of sound occurs in different ways depending on the medium: in water, due to its higher density, mechanical waves propagate about 4.8 times faster than in the air. Therefore, the ability to detect vibrational stimuli in the water provides animals a great source of information about the environment. Chondrichthyes perceive low-frequency stimuli through their inner ears and the lateral line system, but it is difficult to discriminate the vibration perception between these two systems. Both systems are part of mechanoreception, playing an important role in chondrichthyan orientation on the environment, participating in currents and hydrodynamic imaging to locate objects (Coombs and Montgomery 1999), besides prey and predator detection.

### Acoustic Signals

The inner ear of chondrichthyans presents three sac-like structures at the base of the labyrinth (the lagena, sacculus, and utricle), and two of them are involved in hearing. Inside those structures, hair cells, the *macula neglecta*, and otoconial masses are responsible for transducing external vibrations into electric nerve impulses, participating in the understanding of acoustic signals. Otoconia are also sensitive to accelerations produced by a sound field, helping chondrichthyans to localize sound sources; besides, hair cells move against otoconia of different shapes and sizes, allowing the perception of sound information differing in direction and frequency. The *macula neglecta*, otherwise, is present in the posterior canal ducts of the semicircular canals, and this structure's variation appears to be linked to foraging behavior (Corwin 1978).

Surface piscivorous elasmobranchs tend to have better hearing than deep-sea elasmobranchs due to the presence of a larger sound detection structure (Myrberg 2001). A laboratory experiment showed, through detected behaviors and audiograms, that the tested piscivorous elasmobranchs can detect and be attracted to low-frequency sounds (Myrberg 2001). Furthermore, blacktip sharks' (*Carcharhinus tilstoni*) vestibular hair cells can detect hydrostatic pressure

variations from storms (Heupel et al. 2003). Despite having specializations for sound detection, communication using acoustic signals is not known in chimeras so far (Lisney 2010).

### Laterosensory System Perception

Located around the snout and along the lateral midline, Chondrichthyes present a lateral line canal bearing neuromast organs. These organs are bundles of hair and support cells covered by a gelatinous cupula that are stimulated by water movement or pressure, working as a “distant touch” that enables the detection of water waves compression. Because canals’ neuromasts detect movements generated by other organisms disturbing the water, small-scale flows and pressure changes allow chondrichthyans to navigate, locate prey and predators, and interact with conspecifics during social behaviors (Hueter et al. 2004). There is also some evidence that the lateral line canal system could participate in acoustic detection of low-frequency vibrations (Montgomery et al. 2009). Neuromasts of non-pored canals, contrarily, may function in the tactile perception of contact with the substrate, prey, or conspecifics during social interaction (Gardiner et al. 2012; Maruska 2001).

## Chemical Communication

Chemoreception plays an important role in the behavior of sharks, rays, and chimeras. Odor detection is essential for prey location, navigation, and sexual behavior, linked to the detection of pheromones during reproduction (entry ► “Pheromone”).

### Olfactory Signals

Chondrichthyan olfactory organs are located in chambers at the side, or a sac at the ventral surface of the head, where olfactory hair cells and microvilli are responsible for receiving and transducing chemical signals from the external environment.

When comparing chondrichthyans’ species, olfactory lamellae occur in a smaller number in chimeras, resulting in lower olfactory sensitivity (Boisvert et al. 2019). However, larger olfactory

bulbs configure greater olfactory sensitivity and are present mainly in pelagic, oceanic, and coastal sharks, all of which have a high dependence on smell for migration over long distances (Boisvert et al. 2019). Furthermore, the internostril distance plays a role in directional olfactory detection, in such a way that, when a smell is stronger in one nostril than the other, the animal can orient itself better in the direction of the signal.

### Gustatory Signals

Gustation is related to the chemoreception in body parts that are related to food intake and handling (orobranchial region), being perceived through the oral papillae (which present taste buds and oral denticles). The abundance and distribution of oral papillae might correlate to feeding habits, capturing strategies, and prey processing. The taste buds can be used to find out if a target is a potential prey or not, meeting the criterion for a recognition bite.

Rays with more general diets (entry ► “Chondrichthyes Diet”) have fewer taste buds and comparatively more oral denticles, which is related to a less-specific prey selection (Boisvert et al. 2019). Dissimilarly, some sharks present larger quantities of oral papillae throughout the mouth and in the pharyngeal region, related to a more restricted diet and more specific prey recognition (Boisvert et al. 2019). In chimeras, recent studies show the presence of a palatal organ with low density of taste buds, probably involved in food selection (Ferrando et al. 2016).

## Tactile Communication

For many animals, the act of touching something becomes essential for recognition, communication, and action. In Chondrichthyes, the way to perform this action is directly related to their mouth, that is, the bite.

Altogether with gustation perception, chondrichthyans may use bites for target recognition. In addition, some sharks bite during feeding frenzy: intraspecific biting may work as an agonistic communication during feeding and is common due to the dietary overlap of the competitors (Carrier et al. 2012).

Another biting communication is present during copulation. Among male elasmobranchs, the act of biting to hold a female appears to be universal (Pratt and Carrier 2001). In most observed species, the male elasmobranch bites the female to hold her in a pre-copulatory act, maintaining adequate position and proximity for clasper insertion (Springer 1967). Usually, those bites occur on the fins and flanks. The biting of female sharks on males can also occur during copulation, probably to synchronize the mating sequence and indicate a sexual hierarchy (Gilmore et al. 1983).

## Electrical Communication

Electroreception in Chondrichthyes is due to modified neuromast organs that form a modified ampullary organ, frequently referred to as the ampullae of Lorenzini, that is exquisitely sensitive to low-frequency electric stimuli and detects electric fields of abiotic or biotic origin (Hueter et al. 2004). The electroreception system in chondrichthyans can be divided into two types: passive electroreception, which consists of the detection of low-frequency and continuous current fields, and active electroreception, in which the animal itself presents structures that generate electrical discharges for the perception of the environment (Crampton 2019). Passive electroreception is used for prey detection, recognition of intraspecific communication signals, and environmental orientation, including ocean orientation based on Earth's electromagnetic fields, allowing elasmobranchs to capture information about buoyancy and direction of movements in general (Kramer 1996). Active electroreception, otherwise, can be used to perceive the environment (detecting changes in the electric field generated by the individual itself) but may also play a role in interspecific recognition (Kramer 1996). Nevertheless, the role of electroreception in chondrichthyan communication and navigation appears to be of importance, since the region of electroreception information integration at the telencephalon is usually enlarged (Lisney 2010).

## Conclusion

Chondrichthyes have a wide spectrum of communication behaviors, defined as the interaction between a sender and a receiver (that can be conspecifics or from different species) through a signal. Despite being still poorly understood, within the group there are five communication modes: visual, acoustic and mechanoreception, chemical, tactile, and electrical. Among these modes, there are behaviors related to chondrichthyans' postures, skin color and camouflage, light emission, acoustic and water movement perception, olfactory and gustatory awareness, touch recognition, and electrical perception. However, most of the published behavior studies target just a few species, so that morphological and physiological studies are the main sources of information about Chondrichthyes' communication. Besides, among Chondrichthyes, sharks receive more attention than rays and chimeras in behavioral studies, implying these last groups should be the focus of future studies for new insights on the topic. Therefore, communication in Chondrichthyes presents itself as a broad and valuable field for the consolidation of new research.

Consumption; Feeding; Food; Prey

### Introduction

The class chondrichthyes comprises the sharks, skates, rays, and chimera. Characteristically these fishes lack bone, instead possessing a partly calcified cartilaginous skeleton (Berkovitz and Shellis 2017), giving rise to the name cartilaginous fishes. There are currently in excess of 1200 extant chondrichthyan species globally (Marra et al. 2017). Their evolutionary history dates back to between 400 and 450 million years (Wilga et al. 2007), and they can be classified into Holocephali (chimeras) and Elasmobranchii (sharks and rays), with further subdivisions into Selachii (sharks) and Batoidea (skates and rays) (Compagno et al. 2005). This class of fishes shows a diverse array of morphological, behavioral, and ecological adaptations. They are found globally in both marine and freshwater systems, and the range of their feeding strategies that have shown to be as diverse as the species themselves is of note.

Historically, members of this class of fishes were deemed to be opportunistic feeders (Huber et al. 2019). However, this interpretation has been shown to be incorrect for many species and many have specialised feeding mechanisms that allow them to consume specific prey items. There are a number of feeding mechanisms employed by chondrichthyan species including the use of suction feeding, ram feeding, biting and filter feeding (Moss 1977; Frazzetta 1994), and these are largely influenced by the ecology and behavior of specific species (Huber et al. 2019). Studies on diet within the class chondrichthyes have led to a better

understanding of patterns of migration and movement and have provided insight into the sexual segregation of many species within this class. In addition, the understanding of the dietary requirements for chondrichthyan species can help to inform a better understanding of the trophic interactions of many systems.

It is well documented that species within the chondrichthyes feed at all trophic levels, from plankton through to large marine mammals (Motta and Wilga 2001). Some species have very specific prey preferences. The lemon shark (*Negaprion brevirostris*) was found to prey mainly on teleost fish, while other species, such as the blue shark (*Prionace glauca*), exhibit a more generalist feeding strategy (Harvey 1989; Cortés 1997). Understanding the diet preferences of chondrichthyan species is complex and changes in diet can occur not just specifically between species, but also ontogenetically, seasonally or geographically within a species (Cortés 1997; Heithaus 2004). The tiger shark (*Galeocerdo cuvieri*) is one such example and is generally considered an opportunistic feeder. This species has been shown to demonstrate an ontogenetic dietary shift. As juveniles the diet consists largely of teleosts and cephalopods with the diet encompassing a wider range of prey items including elasmobranchs, turtles, and crustaceans as individuals mature (Motta and Wilga 2001). The school shark (*Galeorhinus galeus*) was found to exhibit both an ontogenetically and seasonally varied diet with both juveniles and adults showing diverse consumption. Juveniles were shown to prey largely on benthic invertebrates, while adults consumed mainly squid (Lucifora et al. 2006). Prey selection within this species also found to change throughout the year with benthic teleosts being the main prey item for adults from December to February, with increased consumption of squid again from March to April (Lucifora et al. 2006).

It has been documented that feeding in some chondrichthyan species does not take place consistently, but occurs in short bursts. These are often followed by a period of reduced feeding while the consumed prey are digested (Weatherbee and Cortes 2004). This is certainly

true for many of the larger sharks and early reports suggested that sharks generally consume between 3 and 14% of their body weight per week (Budker 1971). The dietary intakes of many more chondrichthyan species have been studied since this report and estimates have been given for weekly intake values for a number of species. For elasmobranch species these values range between 0.2% and 4.34%  $\text{bw}^{-1}$  (Weatherbee and Cortes 2004). Many of these figures are derived from captive species, where observations of feeding can be made. Pups of captive broadnose sevengill sharks (*Notorynchus maculatus*) consumed approximately 2% body weight in food daily, whereas juveniles and adults had a much lower rate of consumption at 0.6% and 0.2% body weight per day respectively (Van Dykhuizen and Mollet 1992). Few estimates of food intake for holocephalans have been proposed due to limited specimens in captivity. However, daily consumption rate of the cockfish (*Callorhynchus callorhynchus*) estimated that an adult would consume approximately 1.4% of its body weight per week, similar to those figures calculated for a cold-water elasmobranch species (Di Giacomio et al. 1994).

## Filter Feeders

It is widely recognized that some of the largest species of fish on the planet consume planktonic organisms. There are currently noted to be 13 filter feeding species within the class chondrichthyes. The whale shark (*Rhincodon typus*), basking shark (*Cetorhinus maximus*), megamouth shark (*Megachasma pelagios*), manta ray (*Manta birostris*), and all nine species of devil ray (genus *Mobula*). Despite demonstrating a characteristic method for consuming prey the mechanisms by which these species feed has been shown to vary as has the target prey. For such large organisms it is clear that individuals require high density patches of prey to make feeding viable energetically (Rohner et al. 2013). Increasingly the diets of these species are being studied in order to better understand the evolution and ecology of the study organisms. Specific

feeding behaviors exhibited by a number of large chondrichthyan species have helped to explain some of the patterns of movement demonstrated in certain populations.

Multiple studies have been carried out for the largest fish in the ocean, *R. typus*. One such study observed ram filter feeding in *R. typus* in the Yucatan Peninsula, Mexico, which is considered the largest site of whale shark aggregations globally (Motta et al. 2010). The sharks were observed to seemingly seek out aggregations of plankton containing the largest organisms and would repeatedly turn to remain in contact with densely populated aggregations of plankton. Plankton samples collected around the feeding sharks indicated that the sharks were targeting aggregations that were dominated by a range of planktonic organisms that included sergestid shrimp, calanoid copepods, chaetognaths, and fish larvae (Motta et al. 2010). Plankton samples taken from up to 10 km away from where the sharks were observed to feed were found to contain aggregations dominated by calanoid copepods, fish larvae sergestid shrimp and chaetognaths (arrow worms), suggesting that sergestid shrimp are a crucial element of the diet for this species.

Similar observations were made for *R. typus* captured off the coast in Tanzania. Analyses of the stomach contents determined that mysid and sergestid shrimp along with copepods were the main prey item found in the stomachs of these individuals (Rohner et al. 2013). An interesting observation made during this study is that *R. typus* was found to shift their diet diurnally, presumably to fully utilize the varying nutritional availability, feeding at the surface in coastal waters while remaining close to shore and feeding in deeper waters on deep-water zooplankton and fishes when undertaking long distance migrations (Rohner et al. 2013). Further to these findings Borrell et al. (2011) suggested that not only do *R. typus* show diversity of feeding with proximity to the shore, but observations based on a small number of specimens suggest that this species could possibly show differences in diet based on sex.

It would appear from the literature that *R. typus* also shows specific and targeted feeding at certain

times of year to maximally utilize the prey that are available. *R. typus* observed in the Gulf of Mexico were noted to feed in areas rich with mid-embryonic phase fish eggs, with  $5 \times$  higher levels of fish eggs recorded in the water where feeding took place than at control sites (Hoffmayer et al. 2007). Similar findings were reported by (de la Parra et al. 2011) who studied the Afuera aggregation of whale sharks, north of Cabo Catoche, off Isla Holbox on the Yucatán Peninsula of Mexico. The research also discovered that *R. typus* was feeding on aggregations of fish eggs. Genetic analyses of the fish eggs in both studies revealed that the eggs were little tunny (*Euthynnus alletteratus*) and it was surmised by Hoffmayer et al. (2007) that the feeding by *R. typus* was timed to coincide with the spawning of *E. alletteratus* given the developmental stage of the embryos. Aggregations of *R. typus* in Belize were also observed to feed on newly spawned fish eggs, including those of cubera snappers (*Lutjanus cyanopterus*) and dog snappers (*Lutjanus jocu*) (Heyman et al. 2001).

The same feeding patterns have been observed for other megaplanktivores. The second largest fish in the sea, *C. maximus*, were observed to forage in relation to thermal fronts, actively feeding in areas where dense aggregations of zooplankton were observed, remaining for up to 27 h within large aggregations of zooplankton that exceeded  $1 \text{ g m}^{-3}$  (Sims and Quayle 1998). Basking sharks were also observed to surface-feed on aggregations of calanoid copepod that are 2.5 times as dense ( $\sim 1500$  organisms per  $\text{m}^3$ ) and 50% longer ( $\sim 2 \text{ mm}$ ) compared to areas where feeding doesn't take place. It seems that *C. maximus* will selectively forage for specific aggregations of their preferred zooplankton species (Sims and Quayle 1998) and appear to be highly specialized feeders (Sims and Merrett 1997). Such is the specific nature of the feeding that *C. maximus* were also found to demonstrate diel vertical migration (DVM) reportedly in response to prey densities. It appears that *C. maximus* feed on copepods (*Calanus* spp.) and euphausiids (krill) and follow the diurnal movements to actively feed on these species (Sims et al. 2005). Other studies suggest that

*C. maximus* favor *Calanus* as a preferred prey item. Plankton samples collected close to feeding individuals in the English Channel off Plymouth were shown to be dominated by calanoid copepods, specifically *Calanus helgolandicus* (Sims and Merrett 1997).

The diet of several ray species have also been examined and in some species similar feeding patterns to *C. maximus* were observed, whereby one prey item dominated the diet. Almost 62% of the diet of the reef manta ray (*Manta alfredi*) was found to consist of calanoid copepods, whereby it appears to actively seek out large aggregations of these species (Bennett et al. 2016). The bentfin devil ray (*Mobula thurstoni*) and spinetail devil ray (*Mobula japonica*) in the Southwest coast of the Gulf of California were found to feed mainly on *Nyctiphanes simplex*, the most abundant euphausiid in the seas of that area (Sampson et al. 2010). The stomach contents of the giant manta ray (*Manta birostris*), Chilean devil ray (*Mobula tarapacana*), spinetail devil ray (*Mobula japonica*), and smoothtail devil ray (*Mobula thurstoni*) from the Bohol Sea, Philippines were examined, and no trophic separation between the species was found with 91% of examined stomachs containing the krill, *Euphausia diomedea* (Rohner et al. 2017). This suggests that planktivorous rays also follow a pattern of discriminate feeding, seeking out dense aggregations of larger individuals of their favored prey.

## Pelagic Feeders

Despite all megaplanktivores within the class chondrichthyes feeding pelagically the mechanisms by which they harvest prey differ significantly from those that actively hunt highly motile organisms. Many chondrichthyan species inhabit the pelagic zones of the world's oceans and hunt larger prey items. Determination of the diet of chondrichthyans that forage in open water and consume larger prey has proven to be more complex than it first appeared. Much of the information is determined from analyses of the stomach contents of captured sharks with few visual

observations of feeding activity. The information on diets for open-water chondrichthyan species is relatively scarce, but what is apparent is that most of those studied were found to have consumed a variety of prey items, but in most cases teleost fishes dominated the diet. Notable among the research is that alongside a mainly piscivorous diet many species were also found to consume cephalopod species, mainly pelagic squid. Dietary overlap was discovered for several species of pelagic shark (bronze whalers (*Carcharhinus brachyurus*), dusky sharks (*Carcharhinus obscurus*), and smooth hammerheads (*Sphyrna zygaena*)) (Rogers et al. 2012). However, in some species which are highly migratory, including the common thresher (*Alopias vulpinus*) and the shortfin mako (*Isurus oxyrinchus*), the diet appears more specialized.

Some species, such as the white shark (*Carcharodon carcharias*) and the tiger shark (*Galeocerdo cuvier*) were found to be versatile in their feeding, consuming a wide range of prey items. A recent report into the diet of *G. cuvier* noted the presence of up to 10 species of terrestrial passerine bird in 39% of the sharks examined (Drymon et al. 2019) an unexpected finding considering the aquatic prey available. It is also of note that in some species, such as *C. carcharias*, there is an ontogenetic shift with smaller sharks consuming a different diet from that of adults. It has been observed that individuals up to 3 m in length tended to prey predominantly on fish, whereas beyond this size diet was dominated by pinnipeds and cetaceans (Tricas and McCosker 1984). Other research has concurred with these findings but note that in some cases *C. carcharias* above 5 m in length have been shown to contain only teleost fish and chondrichthyan species in their stomachs, often as a result of limited availability of marine mammal prey (Malcolm et al. 2001). The same ontogenetic shift in diet has been noted for *G. cuvier*. As the length of the sharks increased, the incidence of teleost and cephalopod prey items was found to decrease, with larger sharks preying on elasmobranchs, turtles, land mammals and crustaceans (Lowe et al. 1996). What is clear from the literature is that most chondrichthyan species that feed in open water

will diversify their diet depending on the availability of food. This diversity of feeding has been noted in a number of pelagic species belonging to the class chondrichthyes. The studies comprise investigations mainly into the diets of shark species as this group of fishes has many species that form part of pelagic communities. These species are able to chase and hunt down prey and have adapted to feed on faster-moving individuals.

Research carried out on thresher sharks has shown that the diet is largely dominated by teleost fish (Smith et al. 2008). *A. vulpinus* is noted to feed on small- to medium-sized fish, including anchovy, hake, mackerel and sardine and will supplement its diet with pelagic invertebrates, such as squid (Smith et al. 2008). Investigations into the stomach contents of 165 *A. vulpinus*, captured off the Californian coast, concur with this. Northern anchovy (*Engraulis mordax*) constituted the main prey, followed by Pacific hake (*Merluccius productus*), Pacific mackerel (*Scowbey japonicus*), and Pacific sardine (*Sardinops sagax*) (Preti et al. 2001). Market squid (*Loligo opalexens*) and pelagic red crab (*Pleuroncodes planipes*) were also found to have been consumed (Preti et al. 2001) but in much less quantity and fewer individuals. Further investigation into the stomach contents of 225 *A. vulpinus*, captured in the Californian current, recorded *E. mordax* to be the most highly consumed prey item, followed by Chilean pilchard (*Sardinops sagax*) (Preti et al. 2012). Similar to earlier findings by Preti et al. (2001) the research also revealed the presence of other teleost species including *M. productus* and *S. japonicus* plus two cephalopod species, *Loligo opalexens* and the jumbo squid (*Dosidicus gigas*) (Preti et al. 2012).

Similarly, the big eye thresher (*Alopias superciliosus*) is noted to feed on hake, squid, scombrids (mackerels and tunas), alepisaurids (lancetfish), clupeids (herrings and sardines), istiophorids (marlin), and elasmobranchs (Smith et al. 2008). Research into the stomach contents of 28 individuals captured off the coast of California noted that teleosts of the family barracudinas (Paralepididae) were the most consumed prey and considered the most important (Preti et al.

2008). This was followed by *M. productus*, Pacific saury (*Cololabis saira*), *S. japonicus*, and *E. mordax*. In contrast to the stomach contents of *A. vulpinus*, eight taxa of cephalopods were identified, with *D. gigas* being the dominant cephalopod prey (Preti et al. 2008). In contrast to this research carried out on specimens of *Alopias* spp. from Peru found that the stomach contents of 128 thresher sharks showed a diet consisting of prey from 10 taxa, but suggested that the diet was generally dominated by *D. gigas* (González-Pestana et al. 2019).

Studies on the stomach contents of another pelagic species, the shortfin mako, have determined that there is geographical separation in terms of diet for this species. According to the research, specimens of *I. oxyrinchus* from the Northwest Atlantic and Australia followed a similar pattern to that of the thresher sharks, consisting mainly of teleost fishes and cephalopods (Stillwell and Kohler 1982; Stevens 1984; Maia et al. 2006). For some specimens sampled off the Australian coast it was noted that large pelagic teleost and cephalopod prey dominated, although a variety of other species were noted including scombrids and short beaked common dolphin (*Delphinus delphis*) (Rogers et al. 2012). Specimens of *I. oxyrinchus* sampled off the coast of California were found to differ in their consumption, with *D. gigas* being of higher importance, followed by *C. saira* (Preti et al. 2012). Other prey were also detected in these specimens with sardines, mackerel, and mullet being present. In addition, several individuals had been observed to consume elasmobranchs, including blue sharks (*Prionace glauca*) and marine mammals including *D. delphis* (Preti et al. 2012). In contrast, shortfin makos captured off the coast of South Africa were found to consume prey dominated by small elasmobranchs, which constituted almost 80% of the stomach contents of those specimens examined (Cliff et al. 1990).

The diet of the white shark has been well studied and it is known to be a versatile predator. As the third largest extant fish species, adult *C. carcharias* require high energy inputs to maintain growth and functionality. Much research has been undertaken into the feeding habits of

*C. carcharias* which have led to a much greater understanding of the ecology and behavior of this species. As previously noted smaller individuals consume prey consisting mainly of fish (Tricas and McCosker 1984) including both demersal and pelagic teleost species (Casey and Pratt 1985). Specimens of *C. carcharias* recovered from beach protection shark nets in South Africa were shown to consume a diverse range of prey from a number of functional groups, including elasmobranch, mammals, teleosts, and cephalopods (Hussey et al. 2012). Juvenile and adult *C. carcharias* have also been shown to scavenge on carcasses of whales (Carey et al. 1982; McCosker 1985; Long and Jones 1996; Dudley et al. 2000; Dicken 2008; Fallows et al. 2013) further demonstrating their opportunistic nature.

There are a large number of pelagic shark species that have been investigated in terms of diet preferences and many of these have similar feeding strategies, whereby the preferred food items consist of teleost fish, followed by cephalopods. The porbeagle (*Lamna lamna*) (Francis et al. 2008) and blue shark (Nakano and Stevens 2008) are two of note that have been widely studied. Other less well studied pelagic species appear to have a more defined piscivorous diet, such as the silky shark (*Carcharhinus falciformis*) (Compagno 1984), which has been noted to consume a wide range of species fish species including yellowfin tuna (*Thunnus albacares*), albacore (*Thunnus alalunga*), and scomber species (Bonfil 2008). The oceanic white tip (*Carcharhinus longimanus*) has also been shown to consume a wide variety of fish species, but more diverse taxa have been observed in the stomach of this species, including stingrays, seabirds, turtles, and marine gastropods and crustaceans (Compagno 1984). It would appear that for most pelagic feeding chondrichthyes teleost fishes alongside cephalopods are the mainstay of their diets, supplemented by a number of other taxa as opportunity presents itself.

## Benthic and Demersal Feeders

A large number of sharks, skates, rays, and chimaera are benthic and feed on or above the seabed.

These feeding strategies often result in a diversity of feeding. Some small benthic shark species are known to scavenge and the lesser-spotted catshark (*Scyliorhinus canicula*) has been shown to feed widely on the discards from fishing vessels (Olaso et al. 1998). The diverse range of feeding strategies allow members of the class chondrichthyes to adapt to a range of habitats globally and means that many benthic species are highly adapted to a number of environments.

Food consumption in the chimera has been little studied, mainly due to the fact that many species occur at depths below 500 m, although several reports do exist. It appears that many species within the Holocephali feed on the epibenthos, indicating a benthic lifestyle. The stomach contents of the cockfish (*Callorhynchus callorynchus*) captured in the northern San Matías Gulf, Argentine Patagonia were examined, with 50% of prey consumed consisting of scallops with a wide variety of other taxa making up the rest of the diet (Di Giácomo et al. 1994). The diet of the rabbitfish (*Chimaera monstrosa*) has been studied from specimens from the Mediterranean and New Zealand. Individuals from New Zealand were found to prey upon a wide range of organisms which comprised echinoderms, decapods, crustaceans, and polychaetes with evidence of consumption of infaunal species (Macpherson 1980). Didier (1998) examined the stomach contents of the *C. monstrosa* from the Mediterranean and noted that marine worms and mussels dominated the diet of this population. The stomach contents of the ratfish (*Hydrolagus collieri*) suggest that like many benthic species they consume a wide spectrum of food items. It was noted that smaller individuals had a more specialized diet, feeding largely on polychaetes, with a wider range of taxa found in the stomach of adults (Quinn et al. 1980). Decapods, bivalves, crustaceans, mollusks, annelids, echinoderms and algae were identified (Quinn et al. 1980). The cape elephantfish (*Callorhynchus capensis*) also demonstrated a wide dietary preference, preying mostly on benthic invertebrates. Remains of many taxonomic groups were found in stomach contents, including bivalves, crustaceans, gastropods, sea urchins, polychaetes and teleost fishes (Freer and Griffiths

1993). It appears that from every report of the dietary intake of chimera that these are diverse feeders and will adapt their feeding strategies to suit the availability of prey.

A review of the published literature revealed that most skate species show a dietary preference predominantly of decapods and fishes, followed by amphipods and polychaetes (Ebert and Bizzarro 2007). Two skate species from the Western Mediterranean followed this pattern but differed in their choice of prey. Stomach contents of the blonde ray (*Raja brachyuran*) and the brown ray (*Raja miraletus*) revealed that juvenile *R. brachyuran* fed mostly on crustaceans, but as they matured the diet shifted to become dominated by bony fishes. For the brown ray the diet appeared to remain consistent, with crustaceans being the main prey of all size classes (Follesa et al. 2010). A similar pattern of feeding was also noted in the Antarctic starry skate (*Amblyraja georgiana*). The stomach contents of 206 individuals were examined and the dominant prey, particularly of larger individuals was found to be fish, followed by Antarctic krill (*Euphausia superba*). In addition this species was also shown to have a varied feeding regime with amphipods, polychaetes, and other benthic fauna being identified as having been consumed (Main and Collins 2011). An analysis of the stomach contents of broadnose skate (*Bathyraja brachyurops*) from the coast of Argentina revealed teleost fish as the main part of their diet, followed by isopods (Belleggia et al. 2008). There are a numerous studies on the feeding ecology and behavior of members of the skate family and the feeding preferences show a similar pattern, whereby fish and crustacean species appear to dominate. Once again, a common theme of these fishes is the diversity of feeding habits shown across a number of species.

A large number of benthic shark and ray species found globally have been investigated to determine diet preferences in order to get a better understanding of the ecology of the species studied and to better understand their role in marine ecosystems. Many of these examine depth stratification, size-related feeding, or feeding related to specific habitats. In a study from the Balearic Sea

in the Mediterranean, the stomach contents of eight demersal elasmobranch species, consisting of three shark and 5 batoid species, were examined (Valls et al. 2011). The sharks (velvet belly lanternshark (*Etmopterus spinax*), lesser-spotted catshark (*Scyliorhinus canicula*), and the blackmouth catshark (*Galeus melastomus*)) and rays (common eagle ray (*Myliobatis Aquila*), cuckoo ray (*Leucoraja naevus*), speckled skate (*Raja polystigma*), brown ray (*Raja miraletus*), and thornback (*Raja clavata*)) were found to differ slightly in their feeding habits. This was found to relate to the position of the species in relation to the continental shelf and slope. The research regarding habitat position showed differences in feeding strategies, with those species inhabiting the continental shelf consuming prey mostly comprising crustacean and teleost species, while those inhabiting the slopes were found to consume higher densities of euphausiids and cephalopods (Valls et al. 2011). The same trend appears to be apparent in other ray species. The marbled electric ray (*Torpedo marmorata*) from the Northern Mediterranean was found to have a predominantly teleost-based diet, with the presence of some cephalopods observed in the stomachs of some species (Capapé et al. 2007). The thornback ray (*Raja clavata*) also feeds mainly on teleosts although a large part of the diet is made up of crustaceans and cephalopods (Kadri et al. 2014). The research found that *R. clavata* also consumed a number of gastropod and polychaete species, although these were found in much smaller numbers and were found to be consumed only occasionally (Kadri et al. 2014). Ontogenetic shifts in diet have been observed in ray species. The diet of *R. clavata* showed significant changes, with crustaceans constituting the greatest proportion of the diet of smaller rays (Kadri et al. 2014). In the undulate ray (*Raja undulata*) a dietary ontogenetic shift was found to occur based on the length of individuals, classed in to three distinct length groups (200–550 mm; 550–750 mm and 750–1000 mm). The diet was seen to shift as the rays increased in length, with smaller individuals consuming large numbers of small, semi-pelagic fish and larger individuals switching to large benthic prey as they increased in size.

As with the skates, rays, and chimera, a number of shark species are also benthic and feed on demersal or benthic prey. The blackspotted smoothhound (*Mustelus punctulatus*) shows an overlap with a number of ray species where its diet is concerned, consuming mainly crustaceans teleost and mollusk species. Again, the prey consumption is diverse, and a number of taxa are consumed, with polychaete, sipunculid, echinoderm, and tunicate remains discovered in the stomachs of this species. As with many species discussed here there is also an ontogenetic shift in diet as individuals grow with a shift from crustaceans to teleosts and then to mollusks (Saidi et al. 2009). In the epaulette shark (*Hemiscyllium ocellatum*), a stomach content analysis revealed the consumption of five groups of prey item. Worms and crabs were found to be the most consumed groups, constituting over 91% of the diet, with lesser species consumed being shrimps, small fishes and amphipods (Heupel and Bennett 1998). Examination of the stomach contents of the port Jackson shark (*Heterodontus portusjacksoni*) showed that this species is a highly opportunistic feeder and that the dietary intake of this species was high. The research revealed that this species consumed prey from 32 taxa although the diet was dominated by mollusks, teleosts, and cephalopods. As with many other species documented here investigation into ontogenetic shift revealed that diet differed significantly by ontogenetic stage. Juveniles and subadults were shown to have diets made up largely of benthic infauna and epifauna. Adult diets were found to be dominated by demersal/pelagic prey (Powter et al. 2010).

## Conclusion

The examples provided here offer a glimpse into the diets of a number of chondrichthyan species, and many more examples exist within the literature. What is apparent is that far from being opportunistic and mindless predators many species with the class chondrichthyes are rather more sophisticated and selective in their feeding preferences. Many are opportunistic in as far as they will

change their prey depending on environmental, migratory, or geographical factors, but will seek out the most appropriate items to consume given the prey available. In addition, it is clear that for many species there is a clear ontogenetic shift in diets as individuals grow and mature, possibly due to the higher energy requirements of larger individuals. From the literature, it is also evident that there is a clear dietary overlap for a large number of chondrichthyan species and similarities with species that inhabit similar habitats. There also appears to be some diversity in feeding between species that inhabit geographically differing habitats. Many of the studies examined the differences between sexes and depth segregation and the answers here are not as clear-cut. In most cases, the diets did not differ between the sexes, but there were more differences in depth segregation and this relates to the availability of prey within specific environments. What is apparent from the large body of literature available is that members of the class chondrichthyes are extremely efficient and highly adapted predators which has enabled them to survive in a range of diverse habitats.

## Synonyms

Ray locomotion; Shark locomotion; Skate locomotion

## Definition

Movement used by sharks, rays, skates, and chimaeras to traverse their environment.

The class Chondrichthyes is comprised of sharks, rays, skates, and chimaeras. They are among the oldest jawed vertebrate fish (de Bellard 2016). Chondrichthyans are classified as cartilaginous fish because they lack boney structures and instead contain a partially calcified cartilaginous skeletal structure. Historically over 1,200 species have been identified globally, dating as far back as 400–450 million years. The Chondrichthyes class is further divided into two subclasses: *Elasmobranchii* (sharks, rays, skates, and sawfish) and *Holocephali* (chimaeras, or ghost sharks). The *Elasmobranchii* are further subdivided into *Selachii*, or sharks, and *Batoidea*, including skates and rays (Crooks 2019) (Fig. 1). Chondrichthyes have adapted to a variety of water systems globally, including marine and freshwater, and their feeding behavior reflects that diversity. Species within Chondrichthyes are well known to feed at all trophic levels, ranging from plankton to marine mammals (Crooks 2019). As a result of the diversity in geographical location, feeding behavior, and body forms, chondrichthyans have developed a wide variety of locomotive behaviors. This entry will discuss general and alternative modes of locomotion, as well as how the study of these animals has progressed human innovation.

## Major Locomotor Modes

Sharks are highly adapted for high-speed locomotion and precision maneuvering through the water. While there are a great range in body forms, all sharks use generally similar swimming biomechanics. Rotation around the body's longitudinal axis allows all sharks to create wave-like undulations of the caudal fin (Lauder and Wilga 2000) (Fig. 2). The movement of the caudal fin generates force that propels the animal forward. Current literature suggests that the caudal fin, or heterocercal tail, is the most important component of movement for allowing horizontal thrust. This structure is unique because the upward bend of the axis of the notochord creates an asymmetrical shape to the caudal fin (Thomson 1976). The asymmetry of the heterocercal tail, along with the positioning of

**Chondrichthyes Locomotion, Fig. 2** (a) Shark swimming is characterized by longitudinal rotation of the body that creates undulations of the caudal fin in most sharks. This movement generates forward thrust of the animals. (b)

The bluespotted ribbontail ray (*Taeniura lymma*), showing undulations of the pectoral fins that can be seen in a variety of batoid species

the lateral pectoral fins, produces a net upward or “lifting” force. The weight of the fish counteracts this upward force to allow uniform horizontal locomotion (Thomson and Simanek 1977).

The paired pectoral fins, located between the head and caudal fin, likely play a role in ascending, descending, and rolling maneuvers. Through the observation of leopard sharks, *Triakis semifasciatus*, it has been determined that the positioning of the pectoral fins can create positive or negative lift, causing the body angle of the shark

to change and thus resulting in an increase or decrease in depth, respectively (Lauder and Wilga 2000, 2002). Minor changes in the relative positioning of the pectoral fins allow for sharks to make quick and agile maneuvers in the water. The reliance on the caudal fin as a driver of locomotion in sharks may explain the highly adapted shape of this structure. In contrast, the more simplified shape of the pectoral fins may be explained by their use for less drastic changes in relative position of the animal.

Batoidea are a group of cartilaginous fish that are closely related to sharks and are comprised of rays and skates. Anatomically, these organisms differ from sharks in that their bodies are dorso-ventrally compressed with enlarged pectoral fins that span the length of the body and fuse to the head (Hall et al. 2018). As a direct result of this unique body structure, these organisms use their pectoral fins as the main driver of locomotion. Two major locomotive behaviors have been described in these animals. The first, termed “rajiform,” is an undulatory motion of the pectoral fins, and is defined by having multiple waves present on the pectoral fin at a given time (Rosenberger 2001; Breder 1926) (Fig. 2). This behavior is used by skates and rays and appears to be important during feeding and other activities that occur close to the floor of the ocean, as it is not ideal for long-distance swimming (Hall et al. 2018). The second behavior, termed “mobuliform” is an oscillatory “flapping” of the pectoral wings used by manta rays and other pelagic batoids, and is described as having no more than one-half of a wave present on the pectoral fin at a given time (Rosenberger 2001; Webb 1994). With each stroke, the pectoral fin is angled precisely with respect to the water such that it is able to create lift, which in turn translates to propulsion of the animal (Rosenberger and Westneat 1999). This form of movement is specifically advantageous for animals that feed in open waters, as it lends the ability to swim faster and more steadily (Fontanella et al. 2013). While these two swimming patterns have been classified separately, it is likely that organisms utilize a combination of undulation and oscillation on a continuum dependent upon the behavior and locomotive goal of the animal (Rosenberger 2001).

Chimaeras, comprising the group Holocephali, rely solely on their pectoral fins to produce movement (Combes and Daniel 2001). Unlike sharks, the caudal fin remains rigid during swimming and it is not thought to contribute to forward movement (Higham et al. 2018). Moreover, the locomotion of Chimaeras is unique in the fact that both oscillatory and undulatory motions are observed in the pectoral fin movement of these animals (Combes and Daniel 2001). As the pectoral fin is

flapped in an oscillatory manner, an undulatory wave travels down the pectoral fin from anterior to posterior (Combes and Daniel 2001; Wilga and Lauder 2000). A study of the spotted ratfish (Foster and Higham 2010), *Hydrolagus colliei*, suggests that these animals have adapted larger abductor and adductor muscles that are responsible for movement of the pectoral fin, as compared to the spiny dogfish, *Squalus acanthias*. Dogfish, which are more closely related to sharks, rely on undulations of the caudal fin to produce thrust (Foster and Higham 2010; Wilga and Lauder 2002). It is possible that the enhancement of these muscles is necessary to facilitate precision maneuvers while navigating their environment and supports the observations of their reliance on pectoral fins for movement.

Chondrichthyans are widely distributed through the oceans of the world; however, as ocean depth increases, they become scarcer, and are thought to be absent at ocean depths greater than 4,000 m (Priede et al. 2006). One possible explanation (Treberg and Speers-Roesch 2016) for this observation is the reliance on high-speed locomotion for hunting. This requires vast amounts of energy, which may not be available at depths greater than their current zone of habitation. Treberg and Speers-Roesch (2016) also noted that chondrichthyans maintain high levels of lipids in their liver, possibly to control buoyancy and aid in locomotion. The group reported a correlation of increased accumulation of buoyancy-specific lipids, such as squalene, in species that are more suited for deeper water, and higher concentration of energy-specific lipids in shallow water species, that rely on continuous movement to maintain buoyancy. The data presented represents an excellent example of an evolutionary trade-off, and may help explain why a majority of these animals occupy shallower waters where food sources are more abundant.

## Alternative Locomotive Strategies

While sharks are commonly renowned for the speed and agility of their swimming, they also possess some impressive alternative forms of locomotion. Some species of sharks have

specialized their fins such that they can “walk” on the bottom of the ocean. *Hemiscyllium ocellatum*, also known as the epaulette shark, is one such species which uses both its pectoral and pelvic fins for locomotion (Fig. 3). Initial studies into this behavior show that epaulette sharks walk only in short bursts when submerged before they change their direction of movement or speed. Analysis of their gait pattern demonstrates two

important principles. First, the epaulette shark’s locomotion shows alternating function of the pelvic and pectoral fin pairs consistent with a lateral sequence diagonal couplet symmetrical gait pattern (Hildebrand 1989). Second, there is a strong relationship between the movement of the pectoral fin and movement of the head. When the left pelvic fin’s musculature is activated, the right pectoral fin advances, stimulating the head to

**Chondrichthyes Locomotion, Fig. 3** (a) *Hemiscyllium ocellatum*, the epaulette shark, walking on the bottom of the ocean. The animal engages both its pectoral fins and pelvic fins to traverse across the ocean floor. (b) Punting behavior of stingrays. The animal utilizes its pelvic fins,

along with undulation of the pectoral fins, to traverse across the ocean floor. (c) Picture of an AUV, termed MantaDroid, that was inspired by the anatomy of batoids, designed by a team of researchers at the National University of Singapore

move both laterally right toward the pectoral fin and vertically down toward the ocean floor. This triggers subsequent activation of the right pelvic fin, progressing the left pectoral fin forward and leading the head to move back upward to midline, before repeating the downward curvilinear motion to the left. During this process, the head never contacts the ground. In contrast, the tail also exhibits lateral motion with forward pectoral movement, but remains in contact with the ground throughout the cycle. The range of the tail's lateral motion increases with speed of movement, traveling further laterally with faster speeds to prepare for transition into swimming (Pridmore 1994).

Batoids also display an alternate form of locomotion to swimming, which has been described as punting. A punt is a specialized form of locomotion similar to a jump. While batoids propel themselves with their large pectoral fins during swimming, punting is characterized by involvement of their smaller pelvic fins. During the punt, batoids will sweep their pelvic fins anteriorly and plant them into the ground. This maneuver propels the body anteriorly, by pushing off of the bilateral pelvic fins (Macesic et al. 2013). There are two different forms of punting found in batoids distinguished by the extent of involvement of these pelvic fins. "True punting" is done using only the pelvic fins, while "augmented punting" uses both pelvic and pectoral fins for propulsion. True punters rely only on their pelvic fins for propulsion because the musculature surrounding their pelvic fins has undergone greater specialization than that of augmented punters, particularly the propterygium depressors and elevators (Macesic and Kajiura 2010). This enables them to travel further with each punt. Because augmented punters lack specialization of the propterygium muscles, they have developed the compensatory method of supplementing propulsion with the pectoral fin movement. In this technique, the pelvic and pectoral fins activate at the same time, with the pelvic fin pressing into the surface and the pectoral fins undulating in a manner resembling the undulatory swim pattern seen in some species. The pectoral fin reaches maximal height just before the pelvic fins are fully

extended, ending the thrust phase and entering the recovery phase (Macesic et al. 2013) (Fig. 3).

Studies regarding the walking and punting of aquatic species have received significant attention in recent years, as it is believed that the first terrestrial species evolved from underwater walking locomotion before transitioning to land. The alternating left/right movement of the limbs indicate that sharks and rays are likely utilizing ancient neuromuscular patterns that are shared with quadrupedal tetrapods (Jung et al. 2018).

## Locomotor Migrations

The waters of Southeast Florida see an enormous seasonal influx each year as massive aggregations of migrating blacktip sharks (*Carcharhinus limbatus*) enter the nearshore waters in the winter. Over a 4-year period from 2011–2014, shark abundance peaked in the winter (January–March), but by late spring (April–May), it had sharply declined to 1.1% of its peak, where it stagnated until spiking again in January of the following year. Shark abundance was observed to be inversely correlated with water temperature (large numbers found only when water temperatures were below 25 °C) and with the day of the year. Shark migration along the eastern seacoast of the United States has been shown to correspond with the spawning of baitfish species (Kajiura and Tellman 2016).

In the western Atlantic, five Rajidae species show a range of migratory patterns from very little movement in smooth skate and thorny skate to long distance migration in winter skate. Of the five Rajidae species examined in the study, clearnose skate, little skate, and winter skate seem to make longer seasonal migrations compared to species without clear seasonal trends in reproduction. Little skate and winter skate seem to make partial migrations, but further studies are needed to identify if partial migration explains the observed distribution patterns, or if these result from stock-specific migratory behavior. The deep-watered thorny skate and smooth skate do not seem to exhibit strong seasonal migration patterns, and reproduction does not seem

especially related to season. Even though the study professes sparse data usage, its evidence suggests that not only are live-bearing batoids highly migratory, but that also many egg-laying species have complex, moderately long-distance migratory behavior (Frisk 2010). The differences in the migratory patterns of different species of all chondrichthyans in relation to their preferred method of locomotion would be of particular interest for future studies.

## Bioinnovation

The extensive evolutionary history of sharks and rays has allowed them to go through immense evolutionary adaptations to optimize their shape and biomechanics. One way that we can improve the efficiency of our technology is through simulation of these evolutionary adaptations. For example, biomimicry can be used to design and construct structures that are inspired from the natural world. One such example of biomimicry has come from observing shark skin. Sharks display a particular pattern of scale's (denticles) that are designed to affect the lift to drag ratio as they swim. Lift is the aerodynamic force on a body traveling through any fluid, causing the said body to rise. Drag is a force on the object that resists motion, causing friction and reducing the velocity of travel. Lift to drag ratio is important for any structure traveling through a fluid, including helicopters, planes, turbines, and submarines. Low lift to drag ratios negatively affect the ability to travel, increasing energy demands. Shark denticles are plate-like scales with a trident appearance, sporting three ridges, with the central ridge being taller and longer than the lateral ridges. Experiments have shown that airfoils (structures with curved surfaces to give a favorable lift to drag ratio) covered with denticle-like structures could improve the lift to drag ratio by both decreasing drag, and increasing lift, creating vastly heightened ratios (Domel et al. 2018). The lift to drag ratio increase is caused by reduction in contact of the shark to micro turbulent vortices that occur while swimming, which decreases transfer of momentum and shear stress, reducing

drag. This also has another important characteristic; it keeps them naturally clean because it makes it difficult for microorganisms to attach to the skin. This is best seen when comparing older sharks and whales, as the shark's skin still appears smooth and clean whereas barnacles and other growths are often found on aged whales. The unique nature of the denticles is being considered in many fields, including for the manufacturing of medical equipment (Bixler and Bhushan 2013).

Batoids have also provided humans with inspiration for improvement on technology. New autonomous underwater vehicles (AUVs) are inspired by their fast, high efficiency swimming (Fig. 3). These agile movements result from specializations of their pectoral fins, specifically the stiffness of the fin tip, which resist hydrodynamic bending forces while creating large forward propulsion forces (Liu et al. 2015). The pectoral fins are composed of cartilage segments that act as a support system, connecting at joints to form radial elements that originate at the root and extend out toward the edge. Near the tip of the fin, the cartilage segments are organized closer together, lending a greater structural integrity than at the base of the fin and creating their relative rigidity. This is a necessary evolutionary adaptation since the tips of the fins experience the greatest displacement, and therefore the greatest strain levels of the fin. The exact structure of the fin varies between species, but all fins demonstrate a distinctive interradi joint pattern (IRJP) that helps to determine the way the fins move in the water, whether through oscillation or undulation. Current research is still examining the exact mechanism by which IRJP creates these efficient swimming patterns, however, this assessment of the fins' internal structural characteristics has already and will continue to play an important role in understanding underwater kinematics and developing practical mechanical versions of Batoidea fins (Russo et al. 2015).

## Conclusion

The chondrichthyans are a group of organisms that display a wide range of diversity in body morphology and locomotive strategies. Use of

the caudal fin as the main driver of locomotion, as seen in sharks, has been vastly studied, as has pectoral fin locomotion that is seen in the batoids. Within the batoids, the use of undulation versus oscillation of the pectoral fins varies between species and has been linked to be adapted to the animal's aquatic environment. Chimaeras utilize solely pectoral fin locomotion, but have uniquely adapted use of both undulatory and oscillatory motions. In addition to major locomotive motions, various additional locomotive strategies have been studied. The epaulette shark's ability to utilize its pectoral and pelvic fins to traverse the floor of the ocean gives insight into the evolutionary transition of organisms from aquatic to terrestrial environments. The ease at which these organisms traverse their environment has been an inspiration for human innovation to improve our own technology, with various underwater vehicles being adapted directly from their anatomical designs. Continued study of this group of animals will further our knowledge of the vastly unstudied biology of our oceans and the way that organisms have adapted to live there.

<sup>2</sup>Life Sciences, Devi Ahilya Vishwavidyalaya, Indore, India

## Synonyms

Cartilaginous fishes

## Definition

It is a class of fishes whose skeleton is made up of cartilage instead of bone.

## Introduction

Members of the class Chondrichthyes are popularly known as cartilaginous fishes as their skeleton is made up of flexible and soft cartilage which is covered by hard tissue instead of mineralized bones and these include sharks as large as 50 ft long to the most common dogfish of 1–2 ft. The class Chondrichthyes includes batoids (rays, skates, sawfish, and guitarfish) and chimaeras or ratfishes.

Cartilaginous fishes are true fishes having paired fins, and they breathe with gills, each placed in a separate cleft, without operculum over the gills except in Holocephali subclass. The features that distinguish cartilaginous fishes from bony fishes, the Osteichthyes is the presence of paired nostrils on the side of the head that never

open in the mouth cavity and minute tooth like placoid scales present on a tough skin. Almost all the fishes in this group are carnivorous or scavengers: the skates and rays are bottom-living relatives, feeding mostly on invertebrates. Many unique structural, physiological, and behavioral characters make these fishes of particular interest to scientists. These fishes are living fossils, for many of the living sharks and rays are placed in the same genera as species that swam the Cretaceous seas over 100 million years ago.

Classification

| Scientific classification |                |
|---------------------------|----------------|
| Kingdom                   | Animalia       |
| Phylum                    | Chordata       |
| Subphylum                 | Vertebrata     |
| Infra phylum              | Vertebrata     |
| Class                     | Chondrichthyes |

Within the Infra-phylum Gnathostomata, cartilaginous fishes are diverse from all other jawed vertebrates. The class Chondrichthyes includes two significant subclasses – the Holocephali and the Elasmobranchii. Elasmobranchs categorized into the sharks and rays. Sharks are called Selachians and Batoids. The Chondrichthyes are known to have existed from the Devonian period, the so-called Age of Fishes, from 350 to 400 million years ago (evidence present in fossil records).

Selachians

Sharks

There are approximately 350 species of sharks. Sharks possess a graceful streamlined body called fusiform as they swim long distances in open water. They swim haphazardly from back and forth while moving its head laterally. The main characteristics of sharks are a heterocercal tail (in which the upper half is longer than the lower half) which is a modified caudal fin, five to seven-gill slits located behind the mouth for respiration, and a rounded body tapered at both ends. Teeth pointed and sharp fixed in the gums in several

rows not embedded in the jaws; therefore, it easily broke off and replaced smoothly and continuously. The jaws of Selachians not affixed to the cranium. At its anterior end, the pointed snout is called the rostrum that helps in overcoming the resistance of water while swimming. The eyes are similar to that of human although very prominent. Presence of large spiracle, which is the first-gill cleft, posterior to the eyes permitting water passage into the mouth for respiration. Also, there are several pores called ampullae of Lorenzini present around the eyes, nostrils, and snout that sense change in salinity, temperature. and water pressure. Shark feeding habits widely varies. Some sharks like the bull shark or the tiger shark primarily feed on other small sharks. A few sharks like hammerhead sharks are skilled in eating stingrays (Maricapo.edu).

Batoids (Rays, Skates, Guitarfish, and Sawfish)

This group comprises of 470 kinds of species having differences, yet many similar characteristics in common; like its body is flat (also called depressiform) that swims like a flying bird and, mostly, its head is attached to the elongated pectoral fins. These elongated fins look like wings. The geographical distributions of Batoids include almost all the oceans and even freshwater bodies of the tropical region.

Sawfish (*Pristidiformes*) can exceed 7 m (23 ft) in length; they have a long snout lined with saw-like teeth. Guitarfish or shovelnose rays (*Rhinobatiformes*) characterized by a long, thick body and slender like pectoral fins; they mainly feed near to sandy bottom on small invertebrates. Skates are located mostly in deep water; they feed on insects and distinguished by a set of thorns on the tail.

The order Myliobatidiformes contains a different kind of ray. The eagle rays are giant, which needs muscular pectoral fins so that it can swim very fast. Manta rays are known as the largest rays, with the widths of approximately 7 m; like the largest sharks, they bear specialized mouth-parts for feeding on plankton. Stingrays (*Dasyatididae*) have a tail ending with a flexible, whip-like section that equipped with one or more poisonous spines. Torpedo, also known as numb

fishes or generally as electric rays, evolved itself to have muscles which act as an electric organ. This organ so modified in some rays that it is capable of producing 200 volts of electrical current in one single shot, most of these unique creatures found in freshwater bodies only.

### Holocephalans (Chimaeras or Ratfish)

The approximate 25 species of ratfishes are mostly bottom dwellers in some of the deeper marine habitats. They feed primarily on mollusks and different available invertebrates, by crushing their hard shells by the help of its flat teeth. Ratfishes have a voluminous head and eyes. It also characterized by a long, thin tail. They possess an operculum which is a tough bony layer of tissue that keeps the gills covered, which is absent in all other cartilaginous fishes but a significant feature of bony fishes (Heinicke et al. 2009).

## General Features

### Distribution and Abundance

Most of the sharks and rays are marine living fishes, but many of them also found in estuaries; some also travel up to the freshwater bodies like rivers, but a few of the members are permanent residents of freshwater. Most species are found in the moderately shallow waters of the continental shelf or near offshore islands; a few species wander far in the vast spaces of the oceans. Some lives very deep, some in mid-waters or at the bottom; most of them are surface swimmers.

Cartilaginous fishes have adapted themselves in living in all kinds of depths and all aquatic ecosystems, but not yet in the extreme conditions. However, a wide variety of cartilaginous fishes restricted to a particular zone of the ocean. On an average, 50% of species live in the continental slopes, which are up to 200 m, and 35% dwell in the depths between 200 and 2000 m. Only 5% of these fishes inhabit the open ocean. For example, the manta rays go for yearly migrations, while the great white shark (*Carcharodon carcharias*) has known to travel between South Africa and Australia.

The elasmobranchs occupy the broadest range of habitats – even the icy cold waters of the Antarctic and the Arctic Ocean. They cannot tolerate the extreme conditions such as high salinity or the oxygen-deficient depths. Therefore, sharks do not live very deep water.

### Food Habits

#### Sharks

The sharks are carnivorous having plentiful food choices, but there are also some exceptions because of the difference in the size and availability of fish. The most preferred food of the sharks, skates, and stingrays involve sea turtles, squid, sea lions, crustaceans, and dead dogs, and sadly, it can also be garbage that is thrown away from ships.

Individuals usually live alone but sometimes come together as a group to explore food resources or to reproduce. During these mating, some fishes may show particular supremacy structures, generally based on size. When the correct prey discovered, first of all, sharks start circling it, and then appears out of nowhere and approaches from the downside. Eating habit is activated by growing numbers and fast swimming when more than three sharks appear in search of food. All of a sudden, sharks progress encircling the prey by rapid crisscross to make the victim give up.

Sharks have varying biting methods with teeth evolved for sawing and shearing to assist in adequately grabbing along with body motions; this includes rotation of the whole body including turning and twisting movements of the head and tail and furious head vibrations. When the shark comes into position, they protrude their jaws out and locking the teeth into the correct place.

Sharks locate its food by smell. They also possess some other important senses that help them to discover food. Sharks sense their prey by detecting vibrations in the water; for this, they have a series of sensory pores in the sideline of the body. The network of ampullae permits shark to sense even faded electrical signals caused by prey; their eyes so acutely developed that they can easily discriminate the shape, size, and shade of their prey. Altogether, these sensory organs contribute to a well-integrated system for searching for prey.

## Rays

The batoid fish are major bottom dwellers, which prefer prey near to the seafloor. They mainly feed on invertebrates, crustaceans, and mollusks. Whip-tailed rays by the help of their full pectoral fins unearth shellfish from the muddy or sandy surface. Skates capture their food by hovering over it, and then it lay upon them, a habit adapted to hunt appropriately at night.

Electric rays also recognized for their sluggish habit characterizes Torpedinidae as they are bottom-living fish. They eat invertebrates and tiny fish, which are paralyzed by the electric shock produced from their specialized electric organ. They are even capable of eating very active fishes such as eel, dogfish, and salmon because of their ability to generate electricity and wide extensible jaws. Upper-water rays are observed to capture fish by surprisingly raising the front disk of their body while keeping the margins low, in a way forming a hollow cavity and fishes are drawn by powerful inrushing of the water.

Chimaeras and ghost sharks swim near the coastal lines and deep in the waters, to at least 2500 m of depths (about 8000 ft). They are more functional at night, feeding mostly on small fishes.

## Form and Function

The elasmobranchs are fish kind of vertebrates. The fins which are present on its back are known as **dorsal fins**. Many of these fishes possess only a single dorsal fin; others may have two dorsal fins. These fins along with fin spines sturdy and rigid, but not erectile. The dorsal fin acts as a stiff spine in some fishes, and in other, there may not be any spine. A few species are characterized by possessing a poisonous barb on its dorsal fins. These fins provide stability to sharks and help sharks from turning over while swimming. The **caudal fin** that is the strongest and largest fin on the sharks' body helps fish steer without the use of much energy.

The fins that are on the side of the shark are the **pectoral fins**. Pectoral fins used for steering and give the shark lift in the water. They are known as sharks' brakes that act like wings of an aeroplane, and with its help, sharks move backwards and up and down in the water. The **pelvic fin** is found on

the shark's stomach and is used to stabilize the shark in the water. In the male sharks, there may be an organ present called clasper that is used during mating.

The **anal fin** is found between the caudal and pelvic fins on the underside (base of the tail) of the shark. It is usually not found on all sharks. The anal fin is also used for stabilization.

The tail, also known as caudal fin, has an upper and lower part. These two parts look almost the same but differ in size or shape. This tail fin helpful in propelling the shark in the water ([cbfieldstation.org](http://cbfieldstation.org)).

Sharks have an internal cartilaginous skeleton which is robust, flexible, and durable but lightweight. It helps sharks from sinking, and it allows sharks turn in a much tighter radius in the areas in the body where it requires more strength than the other parts, like in jaws and backbones; their cartilage is calcified means calcium salts are present in them.

Some other parts, such as the teeth edging the mouth (beak) of saw sharks and sawfishes, the spines of stingrays are structurally well-advanced scales. They are called rover predators as they can swim more or less continuously when searching for its prey and the body is so structurally developed as it has pointed head, terminal mouth, narrowed caudal peduncles, and forked tails. In the mouth, teeth are arranged in the form of rows just attached through a delicate fibrous membrane over the jaws. As the teeth are not firmly attached so when a tooth broken or accidentally lost, it soon replaced by another tooth, present behind in the next row. Rudimentary teeth are present at the base of the innermost row, and tooth buds developed, and it moves forward when in need.

The body of cartilaginous fishes possesses a lateral line that allows them to sense changes in the pressure of the surrounding water and alert them to move so that they never run into each other. Their tail is a heterocercal tail which is an ancient form of a lunate or crescent shape. These fishes have no swim bladder and are heavy in front that makes its body deliberately downward driving design which supplemented with horizontal, plane like pectoral fins that transformed that downward force into a horizontal, forward driving force.

The rays vary externally from sharks possessing gill openings which are confined only to the lower surface. The eyes of the rays are present on the dorsal surface, and the lateral lines of the pectoral fins are fixed to the head from the sideways just in front of the gill openings. In some rays, scales are absent, and some others variously marked with thorns, prickles, or tubercles, all of these are an advanced form of scales.

The tails of these fishes vary from species to species; some have long tail equipped with toothed spines, a few may have a tail with poison glands. The sawfishes have prolonged snout, but flat and blade-armed on any of the side of the snout with teeth.

The chimaeras possess single gill opening externally. The skin of the adult fishes is smooth on each side of the head, and scales are generally not present; the teeth comprises of six pairs of crushing plates. The dorsal fin and spine are erectile. Male chimaeras too have claspers that act as an organ to transfer sperm in the female cloaca during mating, but they also have a clamping device which is erectile called as the tentaculum, present in front of pelvic fin.

### Equilibrium of Fishes in Water

The typical shark is a long-bodied fish in which the air-filled bladder is absent, which is commonly found in the bony fish, and that is the reason cartilaginous fishes are required to swim continuously to remain afloat. Light oils assist buoyancy in the liver, which can comprise up to 25% of a shark's total body weight and has to, therefore, swim by the passage of waves of contraction along with the metamerically arranged muscles. The sharks are excellent swimmers, where the upturned tail and the fins ensure stability and control of directions. The dorsal lobe of the tail is more significant than its ventral portion and is called as heterocercal and helps the head in keeping in the downward direction. It is corrected by the flattened shape of the head itself and by the pectoral fins, which acts as aerofoils, allowing steering in the horizontal plane. The fins keep them stable as it moves through the water or will enable it to become temporarily unstable and

hence change the direction. To ensure static stability of the body, the fins modified in such a shape that it delivers forces which let the fish move again into its last kind of movement even if it gets deviated in the waters.

### The Skin of Elasmobranchs

These predatory animals are attackers and do not possess a very heavy external armament. The skin is tough covered by layers of the epidermis that feels like sandpaper. Under which lies a thick layer of connective tissue having fibers which are attached to it perpendicularly giving a muscle of high strength and flexibility.

The skin is characterized by a cover of denticles or small rough placoid scales. Each of these consists of a pulp cavity around the edge of which lies a layer of odontoblast secreting the calcareous matter of the scale, known as dentine. The dentine form outside wrapped by the lining of enamel, which is secreted by ectoderm. The scales are similar to teeth, which considered as specialized denticles developed on the skin of the jaws.

The skin of fish provides it protection by the color, secreted by a layer of cells called as chromatophores present below the epidermis. Different types of skin pattern are also observed; some sharks have a wavy or spotted texture that makes them almost invisible when they swim in the water.

### Senses

The sense of smell is very much developed and is the primary means for locating food and helps the predator in moving in the direction of the prey. When a favorable movement of water current is given, sharks are incredibly talented in detecting even minute concentrations or say a fragment of a part per million of particles present in the water bodies, for example, blood.

Their eyes are although functionally and structurally adapted for seeing object or prey, it is noticed that their visual ability to differentiate the color and form of any substance varies among species. It has a tapetum lucidum meaning a reflecting layer Behind retina. This structure is made up of layer of parallel, flat cells filled with crystals of silver guanine that reflects light passed from retina boosting visual signals when there is

low amount of light. Some sharks also develop a nictitating membrane that protects the eye by closing off whenever sharks are feeding or get closer to some object, connected to the eating habits of any species. Predatory sharks which are fast have more accurate and sharp vision, and among some deep-living species, the eyes are accordingly developed to increase detection of encompassing light.

The hearing organ, situated in the cranium to its auditory capsule, is combined with a system of canals that are accountable for equilibrium maintenance. Sharks are remarkably alert to sounds which are even of precise frequency, and to acquire this extraordinary faculty they have the ability for directional hearing. It has not yet confirmed whether the hearing sense is compassionate than the sense of smell.

Sensory organ discovered acts like taste buds are present on the sides, floor, and roof of the mouth or on the tongue, as well as in the throat. Large sharks are capable of discriminating food types – they mostly prefer tuna. However, in some situations, these sharks get out of control, where they attack anything in a frenzy way, even so, attacking its own kind.

Sensory organs are present in the sharks, chimaeras, and rays which receive a high range of vivid information – low frequencies vibrations, salinity, pressure, temperature, and small electrical signals, which are generated by another fish even at a great distance. These sensory organs are situated in the lateral line system, in groups of pores, called ampullary organs, which are capable of detecting electric stimulus found on the head, mouth region, and sometimes near the jaws ([Fisheries and Oceans, DFO](#)).

### Reproductive Behavior

Some of the species of sharks get segregated by sex when they become mature individuals. They come together during the mating period; the larger-sized males become more aggressive and usually stop eating. The sharks get segregated to protect female as a part of their behavioral adaptation. During mating, the principal act used by male fish to start copulation is biting and then gripping the female with teeth. The male holds

female in this particular way so that it can easily insert a clasper, which is a kind of modified fin, into the female genital part called cloaca. When mating is over, both the gender gets separated again. The pregnant female lives in solitude to protect itself from other females of similar size. At the time of parturition, the expecting female moves away to a place which is environmentally suitable for nursery care of the young ones. During the childbirth, the sharks stop feeding and get departed as soon as the parturition completed.

Nursery grounds differ from species to species. The bull shark uses shallow water of the ocean and bays. The spiny dogfish of Atlantic Ocean carries its baby, almost after a couple of years of mating, generally during the winter season, far away on the continental coastal lines of northeastern America.

A few skates which have been noticed mating may also be one of the properties of other rays too. The male ray species holds the female by biting its pectoral fin and then presses its ventral surface against the female while interjecting the clasper, and in some species both the claspers, into her cloaca. Skates possess several claw-shaped spines on both sides of its pectoral fin, which are used for holding female at the time of mating; claw-like spines are of prime importance because they are retractile in the channels of skin.

The eggs of skates have been noticed to be extruded in series, generally of two eggs at a time but sometimes one. Rest periods of at least 5 days occur between extrusions ([Heinicke et al. 2009](#)).

### Respiration

Sharks breathe by opening the mouth while expanding the mouth-throat (buccopharyngeal) cavity and contracting the gill pouches to close the gill slits. With the mouth closed, they contract the buccopharyngeal cavity along with dilating gill pouches. Hence, by drawing the water above the gills, this is the site where the exchange of gases takes place. The mouth remains closed, the fishes contract the gill pouches, and mainly the buccopharyngeal cavity. However, the gill slits are opened to remove the water.

The rays take in water through the spiracles, which gets closed by the contractile movement

generated by anterior margin, which has a similar valve and gill filaments. The water is prevented from entering the throat by the presence of a folded membrane on the floor and roof of the mouth and is directed towards the gill opening. Skates sometimes inhale water through the mouth because it keeps its head a little above from the bottom. Many fishes like stingrays, angel sharks, skates, and guitarfishes reverse the flow of water through the spiracles, for clearing the passage if in case any undesirable foreign particle enters the cavity.

Chimaeras take up the water from the nostrils mainly, during which the mouth remains closed. There is a groove extended from the nostrils, which lead to the mouth, and this groove helps the water enter into the mouth (Cowen 1996).

## Conclusion

Class – Chondrichthyes are those marine animals which possess streamlined structure and have endoskeleton made up of cartilage. The mouth is centrally located. The notochord is present throughout life. Gill slits are disconnected and have no operculum (which is also known as gill-cover). The skin is hard, containing tiny placoid scales. Teeth are qualified placoid scales which are present backwardly. The jaws are mighty. The air bladder is absent, so they are required to swim continuously to avoid sinking. The heart is two-chambered (one ventricle and one auricle).

A few species possess electric organs (e.g., Torpedo) and many of them own poison sting (e.g., Trygon). They are poikilothermous or cold-blooded animals, i.e., they cannot maintain their body temperature. They are monoecious, meaning sexes are different. The fertilization occurs internally, but many of them may be viviparous, e.g., Scoliodon (Dogfish), Carcharodon (Great white shark), and Trygon (Stingray).

## Introduction

The ability of animals to navigate has long been of interest to science and has been widely studied. As far back as 1757, Linnaeus investigated the migratory routes of birds in order to discover how they were able to navigate accurately over long distances. Despite this research lineage, the mechanisms employed by animals to navigate are still relatively poorly understood. There is a large amount of conflicting evidence based on several fundamental issues which means that science cannot satisfactorily explain the mechanisms of long-distance migration (Alerstam 2006). Many

species, including birds, fish, insects, sea turtles, bats, and sea mammals have been shown to accurately navigate over varying distances. Navigation may be considered as short, mid, or long distance and the reasons for making these movements are varied. Food location, mating, egg laying, or live birthing are among those reasons.

The ability to navigate to seemingly specific destinations is still the cause of some speculation. For some terrestrial species, the use of geographical features or landmarks is proffered as a plausible explanation for this to be achieved. The homing pigeon (*Columba livia*) has provided crucial insights into the ability of animals to navigate. Over familiar landscapes *C. livia* has been shown to utilize linear landmarks, such as railway lines, roads, and rivers and they are able to follow these back to their home ranges (Guilford and Biro 2014). True navigation, however, is demonstrated when an animal is able to reach a relatively precise target which is located over a considerable distance without the need for familiar landmarks (Gould and Gould 2012). For longer distance navigational feats, it has been suggested that other mechanisms are at play, including magnetic and celestial cues. In addition it is believed that animals use other senses, such as auditory, visual, gustatory, and olfactory cues. Auditory cues have been attributed to navigation and it is believed that disruption to the auditory navigational map was responsible for the loss of 60,000 homing pigeons lost in 1997 over the English Channel. It appears that the lack of navigational success occurred when the flight path of *C. livia* crossed that of Concorde as it reached supersonic flight. The associated sonic boom is believed to have caused disruption to the pigeon's navigational map causing them to be displaced.

Navigation, in the marine environment is commonplace and occurs within all marine zones, being performed by a large number of species from a range of taxonomic classes. What has really interested scientists is the ability of marine organisms to navigate over long distances, especially those which inhabit a seemingly featureless pelagic environment and can therefore not rely on the associated visual markers available to shallower water species.

In comparison to other species, navigation in organisms belonging to the class chondrichthyes (cartilaginous species comprising the sharks, rays, skates, and chimera) has been relatively little studied and is poorly understood. What is apparent is that there are a variety of mechanisms utilized in the orientation and navigation of chondrichthyan species that allow them to locate themselves over both short and long distances. The chondrichthyes include over 1050 extant species and shows a diverse range of life histories and occur in almost all marine habitats. Many species are benthic and movement occurs over a relatively small area. Other species have been shown to make oceanic migrations over several thousand kilometers. The mechanisms by which chondrichthyan species are able to navigate have been suggested to include the octavolateralis senses (auditory and lateral line system), vision, and electroreception. It would appear that a different sensory array is utilized for different navigational purposes.

### Short-Range Navigation

Short range navigation in chondrichthyan species has been suggested to involve the use of auditory and lateral line senses, as well as vision and olfaction (Montgomery and Walker 2001). It has been suggested that these short range movements are associated with prey and mate location and small-scale movements around territory. Many small shark species, such as the small-spotted catshark, *Scyliorhinus canicula*, are resident across most of their range (Rodríguez-Cabello et al. 2008) showing little movement away from an area. In this case, the visual, olfactory, and octavolateralis senses would be utilized more heavily due to the senses being applied to reactions to environmental stimuli, prey capture, and mate location. Contrary to popular belief many chondrichthyan species have very well-developed visual systems, and it is believed that vision is utilized in navigation (Hart et al. 2006). For some species, or indeed populations, depending on geographic location, vision may not necessarily facilitate accurate migration. For species that inhabit deeper waters

or those that experience high turbidity levels it may be necessary to utilize a different suite of senses and these are thought to dominate. These include olfactory and electrosensory senses that can be an important mechanism to allow for short-range navigation in chondrichthyan species.

## Vision

Very little research that examines vision in chondrichthyan species has focused on the use of vision for navigational purposes. Historically, and until relatively recently, it was believed that vision was poorly developed in chondrichthyan species and evolved specifically for use in dim light. This notion was perceived due to early descriptions of the structure of the retina showing the presence of only rod cells. Rod cells are located on the periphery of the retina and are associated with vision in low light environments. Cone cells, which are clustered in the center of the retina and are responsible for the perception of fine detail and color, were not described in early reports of the eye morphology of cartilaginous fishes. Hart et al. (2006) provide a comprehensive discussion on the morphology of elasmobranch visual apparatus and indicate that far from the early beliefs that chondrichthyan species having poor eyesight that many have well-developed vision. With the exception of several skate species (Ripps and Dowling 1990) and a number of deep dwelling chimera, it has since been discovered that a vast majority of chondrichthyan species possess a both rod and cone cells and many species do in fact have excellent visual capabilities (Lisney et al. 2012). Indeed the white shark (*Carcharodon carcharias*) is thought to have eye sight that is comparable with humans, with many chondrichthyan species far exceeding this. Ablation studies have revealed that many chondrichthyan species rely heavily on their visual sense. This has been noted in smaller species where vision has been found to be important in the location and detection of prey items, conspecifics, and refugia (Hart et al. 2006).

Many chondrichthyan species navigate widely throughout home ranges and experience changes

in light intensity. Several species of shark do carry out diel vertical migrations (DVM) and migrate across a range of light regimes. These migrations can range from tens to many hundreds of meters, occurring at a range of depths from surface waters (Sims et al. 2006) down to the bathypelagic zone (Kyne and Simpfendorfer 2010). One such example is the blue shark (*Prionace glauca*) that has been shown to migrate vertically to depths of below 600 m in under 10 min. This would indicate that species showing DVMs would have to have well-developed eyes in order to adapt rapidly to the changes in light availability at varying depth.

Early studies by Parker (1909) on the dusky smooth-hound (*Mustelus canis*) determined the response of the shark upon severance of the optic nerve. It was discovered that once the optic nerves had been severed that the shark demonstrated a decreased swimming speed and could not orientate itself in the aquarium environment, constantly colliding with solid objects within the enclosure. It was also noted that the individuals that had their optic nerves severed did not recover their ability to navigate within the environment, fundamentally rendering the individual blind. It was also observed that when only one optic nerve was severed the individuals navigated as an unaffected individual would, with only occasional contact with solid objects. Therefore, Parker (1909) concluded that retinal function is important for the orientation and navigation in this species.

Subsequently, research has been carried out on another species of shark to determine the importance of vision as a navigational aid. Lemon sharks (*Negaprion brevirostris*) were the subject of two studies that rendered them temporarily blind in order to determine patterns of movement and behavior. The first carried out by Gilbert (1963) examined the effects of vision on predation while the second observed the homing behavior of visually impaired juvenile *N. brevirostris* (Sundström et al. 2001). In neither case was the navigational ability of *N. brevirostris* seemingly affected when vision had been impaired. It could therefore be considered that the importance of vision as a navigational aid is more crucial in some species than others, and this would depend largely on habitat preferences.

## Olfaction

It is widely recognized that cartilaginous fishes have a highly developed sense of smell and it has long been thought that elasmobranch fishes possess greater olfactory sensitivities than teleost fishes (Meredith and Kajiura 2010). Olfaction in many shark species has been linked to a number of activities including the location of mates (Johnson and Nelson 1978), prey (Schwab and McComb 2007; Gardiner et al. 2014; Yopak et al. 2014), and the avoidance of predators (Rasmussen and Schmidt 1992). Several authors have also suggested that olfaction is used for navigation and homing in many species (Edrén and Gruber 2005; Heupel and Simpfendorfer 2005). However, in relation to the number of studies on the olfactory ability of many cartilaginous species relatively little have considered the role that olfaction plays in navigation. Considering the understanding of the olfactory cues in the navigation of many other species, including avian and teleost species, it is surprising that so little research exists on the role of olfaction on chondrichthyan navigation. This is especially true considering the environmental changes that occur in many marine environments and the disruption to olfactory cues that may occur. It has been noted that not only can aquatic contaminants potentially damage a fishes olfactory organs, but the change in chemical composition of the water may also affect the ability of many species to detect chemical cues within the water body. According to a study by Dixon et al. (2015), ocean acidification can dramatically impact olfaction in shark species, which can lead to an impairment of homing ability. It seems that for some species, olfactory cues play an important role in the navigational process.

In one study, *N. brevirostris* were displaced between 4 km and 16 km from their home ranges, both during the daytime and at night. Although no attempt at causing anosmia was made, the ability of *N. brevirostris* to navigate back to the home range was clear with all specimens, bar one, navigating back to their home range. Although not focused primarily, olfaction observations were made that the water currents were potentially carrying

olfactory cues to the fish, allowing them to orientate back towards the capture sites. This was based on the fact that the animals orientated themselves in a home-oriented direction shortly after release, and it is believed that using the currents as orientation indicated detection of the presence of chemical cues in the water (Edrén and Gruber 2005).

In another study, temporary anosmia was induced in blacktip sharks (*Carcharhinus limbatus*) through the insertion of cotton wool and petroleum jelly into the nares of the study animals (Gardiner et al. 2015). The individuals were then translocated 8 km away from their home range and released. Those individuals where olfaction had been blocked took a significantly longer time to return to the home range than those sharks where no intervention had been made. A similar study to that of Gardiner et al. (2015) was undertaken on the leopard shark (*Triakis semifasciata*). The same method of anosmia was performed and the results demonstrate a clear trend in navigation whereby the sharks released after anosmia had taken place showed a nondirectional pattern of swimming. This is in contrast to the control group whereby the swimming pattern was clearly directional and orientated towards the shore (Nosal et al. 2016).

It has been suggested that the cause of these anosmic behaviors could be due to the size of the olfactory bulb. It would appear that there is a large variation in the size of the olfactory bulb of many shark species (Yopak et al. 2014). It seems evident that the species that possess the largest olfactory bulbs are those that inhabit pelagic waters, such as the great white shark (*Carcharodon carcharias*) which undertake long-distance migrations and possess large olfactory bulbs relative to brain size. This species, amongst others, are proffered to use olfaction as one means of navigation in a seemingly featureless environment.

## Long-Distance Navigation

Although evidence is starting to emerge that cartilaginous fishes use a range of sensory apparatus

to orientate themselves and to navigate over short distances, the instances of long-distance orientation and navigation are still puzzling. As recently as 2001, it was suggested that true navigation was not demonstrated in cartilaginous species. It was also noted that a great deal of speculation surrounded the ability of (elasmobranch) species to utilize sensory mechanisms that allowed large-scale movement (Montgomery and Walker 2001). Many theories have been proffered that suggest a range of environmental cues to enable navigation over longer distances. Celestial cues, tidal patterns, and temperature and pressure gradients are all suggested to play a part, but none has been studied in detail for chondrichthyan species. However, the internal mechanisms used by individuals of this class of fishes are clearly not understood. In 2003, a female white shark was tagged off the coast of South Africa and over a period of 99 days travelled to the coast of Western Australia. The authors clearly state that the mechanisms by which the shark navigated over 11,000 km to Australia and back remain a mystery, especially given the lack of topographical features along the migratory route (Bonfil et al. 2005). However, they do proffer the use of celestial cues as a possible explanation. Despite this lack of understanding of the mechanisms used for long-distance navigation in this species, it appears that members of the chondrichthyes can indeed navigate over long distances and perhaps do demonstrate true navigation.

Much of the literature that reports on long-distance navigation of chondrichthyan species focuses on the concept of geomagnetic orientation. It has been proffered that chondrichthyans could utilize the earth's magnetic field either directly by utilizing biosynthesized magnetite or indirectly by using the highly developed electrosensory system (Montgomery and Walker 2001). The presence of magnetite has been little explored and has so been reported in a handful of chondrichthyan species and has been little studied. The use of the electrosensory system for navigation in chondrichthyes has been more widely studied and seems a plausible explanation for large-scale navigation of this class of fishes.

## Electroreception

Despite being a common attribute amongst many species, electric sense is one of the last of the chondrichthyes senses to be fully understood (von der Emde 1998). As far back as 1687, Lorenzini described the presence and the gross anatomical features of pores on the skin of chondrichthyan species. However, their true function was misunderstood. Lorenzini suggested that they were secretory glands used to cover the body in a gelatinous substance. This misconception was due to the presence of a conductive mucopolysaccharide gel found within the canals of the ampullae. The structure of the ampullae of Lorenzini (AoL) in marine species, which is made up of an ampulla and a subdermal canal that terminates in a single pore on the surface (Sisneros and Tricas 2002), have been well studied and are now better understood. The AoL is now known to have a much more complex function than mere secretion, forming part of the sensory array of chondrichthyan species. It appears that the structure of the AoL is common to most chondrichthyan species, and is located around the head region of sharks and the disc margins in rays, and is visible as small pores.

It was not until the 1930s that the true function of the AoL was first discovered. Observation made by Dijkgraaf in the 1930s noted that specimens of the lesser-spotted catshark (*Scyliorhinus canicula*) were seen to react to a rusty wire in the water (Dijkgraaf and Kalmijn 1962). Since then, it has been discovered that the use of electroreception is varied, being utilized for prey detection (Lim et al. 2010) as well as the location of conspecifics for courtship and reproduction (Crooks and Waring 2013). The electric sense of chondrichthyan species is noted as a short range sense. In *S. canicula*, it is thought to be effective at a range of 15 cm or less (Kalmijn 1971). However, it has been noted that the chondrichthyes have the ability to detect extremely small currents as weak as less than 1 nanovolt per centimeter (Kajiura 2003). It is well known that all living organisms produce minute electrical currents and these are easily detected by the ampullae of Lorenzini once the cartilaginous fish is within range of its prey. It

is this interaction with living organisms that has been the focus of most of the research on electroreception of chondrichthyan species.

However, most chondrichthyan species are also thought to utilize electroreception in navigation. It is noted that members of the class chondrichthyes possess electrosensory capabilities that allow them to detect even the weak electric fields given off by their own bodies as they swim through the earth's magnetic fields (Paulin 1995). It appears that the earth's magnetic field can provide information that can be used to determine position for chondrichthyan species that will allow them to both orientate and navigate (Courtney et al. 2014). Evidence exists that a number of animal species can determine their position based on magnetic fields and as a result many scientists believe that members of the chondrichthyes also navigate using the magnetic fields that encompass the earth (Anderson et al. 2017).

More recently, as an understanding of the ability of cartilaginous fishes to detect the earth's geomagnetic field and electrical currents in the environment is more fully understood, more attention has been given to the detection of weak electrical fields found throughout aquatic environments in relation to chondrichthyan navigation. Many scientists are now hypothesizing that despite being a short-range sense in terms of prey and/or conspecific detection that chondrichthyan species make use of this electroreceptive capability not only to orientate themselves in the water but also to navigate over long distances. Indeed, many behavioral experiments demonstrate the ability of members of the chondrichthyes to detect changes in the geomagnetic field which vary depending on location. It is suggested that many chondrichthyan species can detect the earth's magnetic field (Akoev et al. 1976; Klimley 1993; Kalmijn 1982, 2000; Anderson et al. 2017) and this has led to increasing evidence that for many species the use of a geomagnetic field is the most feasible explanation for long-distance migration (Molteno and Kennedy 2009). This seems especially feasible where topographical landmarks are limited or missing and may help to answer the question of how chondrichthyan species manage to maintain a

direct heading with no other visible cues. It has been hypothesized that scalloped hammerheads (*Sphyrna lewini*) demonstrate a positive topotaxis (Klimley 1993). They have been observed to locate seamounts by traversing ridges and valleys, potentially mapping in relief a geographical area where there are no visual clues. This is believed to aid in swimming direction and orientation of individuals. This is certainly true of the transoceanic journey made by the female white shark from South Africa to Western Australia. Bonfil et al. (2005) note that it is possible that over such long distances in deep waters that the use of the earth's geomagnetic field could offer an explanation as to how an individual is able to navigate, seemingly accurately, over such large, featureless distances.

It appears that the use of the earth's magnetic fields in a highly likely explanation for navigation within the aquatic environment (Paulin 1995). According to Kalmijn (1981, 1984), elasmobranch species may use both an active and passive mode of electroreception when navigating. It is prophesized that as the fish swims voltage gradients are produced within the organism and these are used to orientate in a particular environment. The increase or decrease in voltage away from a magnetic field helps the individual to orientate itself in the desired direction. As it turns away from the magnetic field, there is an increase in voltage and reorientation can take place to maintain a particular heading. Passive mode is theorized to work slightly differently in that the voltage gradient is detected through the body from electrical fields that occur within the environment and which take place through water induction. Kalmijn (2000) summarizes that using both active and passive modes means that it is possible for the organism to simultaneously sense drift within ocean currents with their magnetic compass headings.

However, Paulin (1995) notes that although it appears evident that cartilaginous fishes do use electroreception to navigate, the theories suggested by Kalmijn (1981, 1984) may not be able to account for the biological function of the electrosense in chondrichthyes. It appears that DC voltages cannot be detected by the electroreceptors found within chondrichthyan species.

In addition, Kalmijn (1981) states that the electric sense is used to determine the direction of swimming using fixed reference points by using motion to calibrate movement. Paulin (1995) suggests a theory whereby electroreception provides a compass bearing and neural activity of the shark is utilized in a far greater way than merely detecting changes in voltage by comparing vestibular and electrosensory signals.

Despite this range of evidence, it is clear that there is a great deal of uncertainty as to the exact sensory mechanisms and pathways involved in detecting the earth's magnetic fields (Anderson et al. 2017). In addition, the exact stimuli that are detected remain unclear and the way in which chondrichthyan species are able to fully utilize the magnetic fields across the oceans needs further research to gain a fuller understanding of the mechanisms at play.

## Conclusion

It is clear from the literature that relatively little is known about the mechanisms of navigational capability of members of the class chondrichthyes. What is evidenced is that members of this class of fishes undertake accurate and often long-distance movement and migrations and some species have the ability to navigate over long distances in a seemingly featureless environment. Although there is evidence to suggest that longer distance navigation may involve a complex use of the electrosensory system, the use of other senses should not be ruled out when considering long-distance navigation. Clearly chondrichthyans have very well-developed senses and it would appear that the use of these for navigational purposes is only starting to be understood. The utilization of all senses in combination for orientation and navigation should not be overlooked as there is an evident lack of understanding of the process involved. It would seem that geomagnetic cues are used to guide long-range navigation, while visual or olfactory cues allow animals to pinpoint precise locations within an environment. Very little literature currently exists on the ability of chondrichthyan species to utilize other environmental cues, such as celestial patterns,

temperature, pressure gradients, and gustation to navigate. It would appear that the mechanisms surrounding the navigational processes still need to be better understood, especially in an environment that is being increasingly utilized and changed through anthropogenic activity. According to Montgomery and Walker (2001), more in-depth and structured studies of orientation and navigation in chondrichthyan species is needed in order to lead to a better understanding of navigation in this class of fishes.

### Definition

Chondrichthyes' sensory systems are part of the nervous system responsible for receiving external and internal stimuli and translating them into nerve impulses that are transmitted to the central nervous system where they are processed.

### Introduction

The Chondrichthyes are the basalmost extant branch of Gnathostomata and comprehend a monophyletic group of fishes with fossils and

extant representatives distributed in 65 families with 1282 valid species. Despite several recent findings regarding the relationships of early chondrichthyans (see Maisey et al. 2017 for more information), the extant chondrichthyans are divided into two groups, the Elasmobranchii (sharks, rays, and their kin) and the Holocephali (chimaeras and their kin), and can be recognized by the presence of some apomorphic characteristics, such as prismatic calcification of the cartilaginous endoskeleton, the presence of placoid scales, and pelvic fin modified in claspers in males.

All Chondrichthyes live in aquatic environments (mostly marine ecosystems), and they perceive external (and internal) stimuli through the sensory system, which is the part of the nervous system responsible for receiving the stimuli and translating them into nerve impulses that are transmitted to the central nervous system (entry ► [“Vertebrate Nervous System”](#)) where they are processed.

The life in aquatic environments brings particular conditions to stimuli perception when compared to the terrestrial environment; in such a way, chondrichthyans (as also other aquatic vertebrates (entry ► [“Vertebrates \(Chordata\)”](#))) have some sensory organs more prominent than others, used to navigate their environment (entry ► [“Chondrichthyes Navigation”](#)). For example, chemoreception is largely important in chondrichthyans' perception of the environment, since chemical particles propagate more rapidly in water than in air. Yet, the refractive index of water is close to that of the cornea, so that in aquatic vertebrates the lens is the primary refractive structure in the eye, being almost spherical when compared to terrestrial vertebrates' lens (which tend to be more oval, and the cornea is the primary refractive structure).

The evolutionary success of Chondrichthyes' lineage is in part related to not only their sophisticated battery of sensory organs, but also to Chondrichthyes' morphology (entry ► [“Chondrichthyes Morphology”](#)) and to ecomorphological features (Compagno 1990). However, advances in the understanding of chondrichthyans' sensory biology mostly rely on

information regarding elasmobranchs (see Lisney 2010 for a compilation).

This entry will focus on chondrichthyans' special sensory organs, which are usually localized and respond to specific stimuli. These special sensory organs will be primarily divided by the kind of stimuli, and then by corresponding organ or local: (1) **Chemoreception** (olfaction and gustation); (2) **Photoreception** (vision and parietal organ) (entry ► “[Photoreceptors](#)”); (3) **Mechanoreception** (lateral line system, auditory system, and membranous labyrinth); and (4) **Electroreception** (ampullary organs) (entry ► “[Electroreceptors](#)”).

### Chemoreception

The chemoreceptors are sensory receptors specialized in receiving and translating chemical stimuli. Chemoreception is essential for aquatic animals to identify prey, mates, and habitats, and even avoid predators. The senses commonly associated to chemoreception in vertebrates are olfaction and gustation. Despite olfactory and gustatory receptors perceiving the environment in a similar way, olfactory receptors are distributed in the nasal passage and vomeronasal area, and the gustative are in the oropharyngeal cavity.

### Olfactory System

Olfactory receptors (entry ► “[Olfactory Perception](#)”) are neurons specialized in odorants' detection. The olfactory system of chondrichthyans is essential to locate prey. They develop from paired neurogenic placodes, which invaginate and form

nasal sacs. The walls of the nasal sac form the **olfactory epithelium** which, besides the olfactory receptors, presents basal and sustentacular cells that secrete mucus and support the receptors. **Olfactory sensory cells** bear microvilli at its apical end, while ciliated sensory cells, which are common in other vertebrates, are lacking in this class. The sensory cells send an axon into the **olfactory bulb**, forming the **olfactory nerve**. The olfactory bulb is connected to the olfactory lobes via the **olfactory tract** (Fig. 1).

The olfactory organs of elasmobranchs have rosettes located in the lateral cavities on either side of the snout. These cavities have folds of tissue called lamellae, which are separated by a central raphe and covered by olfactory epithelium. The number of lamellae in this organ can vary between species (see Meredith and Kajiura 2010).

Living chondrichthyans in general are known to excel in their olfaction, this being one of the most prominent (or the most prominent) sensory systems. Some taxa, such as the hammerhead sharks, have an even more significant increase in the area and volume of olfactory organs and, likewise, of their integration region at the brain telencephalon, the olfactory lobes (Fig. 1, left) (Compagno 1990). Differences in olfactory capabilities in elasmobranchs are more related to functional aspects than phylogenetic relationships (Schluessel et al. 2008). Elasmobranchii of benthopelagic habitat has a high number of olfactory lamellae and a larger olfactory epithelial surface than benthic and demersal species. However, no correlation was found between the mass of the

**Chondrichthyes Sensory Systems, Fig. 1** Brain and olfactory organ of a hammerhead shark *Sphyrna lewini* (left) and an Atlantic stingray *Dasyatis sabina* (right).

*Sphyrna lewini* drawing based on Yopak et al. (2015). *Dasyatis sabina* drawing based on Meredith et al. (2013). Scale bars 1 cm

olfactory bulb and the occupied habitat (Schluessel et al. 2008).

Furthermore, some studies indicate that the lateral line system also plays a role (odor-stimulated rheotaxis), together with the olfactory system, in the location of odor source of elasmobranchs.

#### Gustation

Gustatory receptors are chemoreceptors located in the epithelium of body parts involved with food intake and handling, such as the lips, oral cavity, tongue, and pharynx of Chondrichthyes, and are organized in **oral papillae**.

The oral papillae consist of modified epithelial cells and associated receptors, with multicellular peripheral chemoreceptors forming **taste buds**, besides solitary **chemosensory cells**. These structures are usually interspersed with **oral denticles** (reduced placoid scales). Both the oral papillae and denticles feature a phyletic variation regarding morphology and distribution.

Despite the gustation being relatively less studied than other senses (Lisney 2010), the number and distribution of taste buds appear to vary widely among chondrichthyans (Gardiner et al. 2012). A **palatal organ** was described for chimaeras and might have a role in gustation, despite its low taste buds' density. Abundance and distribution of oral papillae and denticles might correlate feeding habits, capture strategies, and prey processing.

#### Photoreception

The photoreceptors are sensory receptors specialized in receiving and translating radiation stimuli. Luminous energy used in Vertebrates' photoreception usually lies between 380 nm (violet) and 760 nm (red) of wavelength. Shorter wavelengths (ultraviolet radiation) are rapidly absorbed by water and not used in aquatic vertebrates' photoreception.

To perceive luminous information, the photoreceptive cells contain a **visual pigment** that absorbs light energy, which initiates a chemical reaction that generates nerve impulses. Differences in light intensity are translated as contrasts, and differences in wavelength are translated as different colors.

The senses commonly associated with photoreception in vertebrates are vision, photoreception regarding the pineal complex, and infrared radiation. Regarding Chondrichthyes, we will deal with **vision** and **pineal complex**.

#### Vision

Chondrichthyes occupy environments with different structures, such as water columns, coastal and ocean areas. Some eye adaptations are correlated to the different light inputs experienced in each environment. Likewise, chondrichthyans that have a vision as a prominent sense also have the processing centers at the brain (such as the optic tectum at the midbrain) notably enlarged.

Chondrichthyes' eyes have no eyelids but might have a **nictitating membrane**, and are arranged laterally or dorsolaterally in its chondrocranium. Since the hammerhead shark has a wing-shaped snout, the eyes are also more elongated, which possibly improves its visual field. Also, some batoid species have eyes situated on the anterior margin of the chondrocranium and oriented parallelly, which provide a frontal view with a binocular overlap.

Remarkably similar to other vertebrates, elasmobranchs' eyes have the following main structures: **anterior chamber, choroid, conjunctiva, cornea, iris, lens, optic nerve, posterior chamber, protractor lens muscle, retina, sclera, and vitreous body** (Fig. 2). In the eyes of Chondrichthyes, as well as other vertebrates adapted to see in low-light conditions, there is a structure called **Tapetum lucidum**. This structure reflects the light that has passed through the photoreceptors back to them and improves visual accuracy in dark environments.

Both **rod** and **cone photoreceptors** are present in most elasmobranchs (except for the skates and some deep-sea or strongly nocturnal sharks, which only have rod photoreceptors), the first being more sensitive than the second, and responsible for vision in dim light (scotopic vision). Sharks are cone monochromats; which means they have only one type of photoreception pigments and are likely color blind. Yet, rays are cone dichromats, having two types of photoreception pigments, with different spectral sensitivities that

### Chondrichthyes Sensory Systems,

**Fig. 2** Generalized chondrichthyan eye. (Redrawn and modified from Kardong (2016))

allow color discrimination (entry ► [“Evolution of Animal Color Vision”](#)) (see Hart 2020).

Chondrichthyes’ visual accommodation (the ability to focus sharply on objects) occurs through the movement of the lens related to the retina. The eye is supported in the orbit by a rod-shaped optic pedicel, and eye movements occur via six extraocular eye muscles. A lateral position of the eyes on the head, combined with moderate eye movements, indicates that for most elasmobranchs each eye has an almost panoramic monocular visual field, with just a small binocular overlap (e.g., Hart 2020).

Considering the body mass, sharks from oceanic areas tend to have relatively larger eyes than sharks from coastal areas (Lisney and Collin 2007). The size of the eye can vary from 60 mm (as in the thresher shark *Alopias superciliosus*, which possesses very large eyes) to 7 mm (Lisney and Collin 2007). Also, meanwhile, some elasmobranch species have continuous eye growth, and others present ontogenetic variation in eye-to-head proportions (Litherland et al. 2009).

In chimaeras, the eyes are the best studied sense organ (Lisney 2010). They are positioned laterally on the head, and due to their relatively larger size in several species, vision might be an important sense to them (Lisney 2010). Chimaeras living in the mesopelagic zone may have

adaptations that either increase sensitivity, as the levels of sunlight diminish with depth, or enhance resolution, allowing localization of small sources of bioluminescence against an otherwise featureless background. Most chimaeras are reported to have a pure rod retina, with a visual pigment that maximally absorbs the wavelengths of light available in deep water. However, species that live in brighter waters are reported to present cones and potentially color vision.

### Pineal Complex

The pineal complex, or median eyes, develops as embryonic outgrowths from diencephalic region of the brain and participates in the detection of light and the physiological adjustments to changes in light levels (as the ones related to day and night cycle). The pineal complex is formed by the pineal and parietal organs, with sensory neurons that extend from them to the brain.

Most extant species of Chondrichthyes have a **reduced pineal organ** (absent in some electric rays, following Studnicka 1905), consisting mainly of a **neuroepithelium with photoreceptors, ganglion cells, supporting cells, glycogen-storing cells, and cytosome-rich cells** (Vigh-Teichmann et al. 1983). Despite not being completely explored for chondrichthyans, some species indicate that the pineal organ might have different responses to light and darkness, besides

correlation to the Gonadotropin-release hormone system (Mandado et al. 2001).

### Mechanoreception

Inner ear regions, membranous labyrinth, and lateral line organs detect different kinds of mechanical stimuli, but they all share the same type of sensory cell: the **mechanosensory hair cells**. Stereocilia (stereovilli) are arranged in a graded series by their height, at the apical surface of hair cells, and are also accompanied by a single kinocilium (a true cilium). The asymmetry provided by different lengths of stereocilia enables the hair cells to respond selectively to mechanical stimuli. Hair cells act like transducers that transform mechanical stimuli into electrical signals which are sent to the central nervous system (Hueter et al. 2004; Kardong 2016). The functional unit of all mechanosensory systems is the **mechanosensory neuromast** (or a modification of this), which is composed of a group of sensory hair cells surrounded by support cells and covered by a gelatinous cupula into which the stereocilia project (Fig. 3).

**Chondrichthyes Sensory Systems, Fig. 3** Neuromast organ, showing the sensory hair cells, supportive cells, gelatinous cupula, and nervous fibers. (Redrawn and modified from Kardong (2016))

### Lateral Line System

The orientation and navigation in water (entry ► “**Chondrichthyes Navigation**”), as well as the ability to detect water movements at multiple scales, are fundamental for fishes, including chondrichthyans. Small-scale flows and pressure changes allow sharks, batoids, and chimaeras to navigate, locate preys and predators, and interact with conspecifics during social behaviors (Hueter et al. 2004). These stimuli are detected by sensory receptors located on the skin, the so-called **mechanosensory lateral line system** (Fig. 4).

The lateral line system is composed of two lateral line canals that extend posteriorly from the endolymphatic pores on the dorsal surface of the head to the tail. Anteriorly, these lateral line canals branch off over the head of chondrichthyans, showing varied degrees of complexity (Maruska 2001; Hueter et al. 2004; Gardiner et al. 2012). The hair cells are oriented parallel to and surrounding the lateral line canal, providing information about the direction in which the animal moves and on water disturbances (Kardong 2016).

Several types of mechanosensory end organs are found in chondrichthyans, differing from each other by morphology and location: **superficial neuromasts** (pit organs or free neuromasts), **pored** and **nonpored canals**, **spiracular organs**, and **vesicles of Savi** (Maruska 2001; Maruska and Tricas 2004; Gardiner et al. 2012). Superficial neuromasts are situated on the skin surface either in grooves on raised papillae, or between modified placoid scales, with their cupula directly exposed to the environment (Gardiner et al. 2012). Sharks and bony fishes differ in the position of superficial neuromast epithelium, and the configuration observed in the former may enhance water flow parallel to the cupula to provide greater directional sensitivity (Hueter et al. 2004; Gardiner et al. 2012).

Pored canals are in contact with the surrounding water via pores on the skin surface and help to detect water movements generated by prey, predators, and conspecifics, and to localize objects while swimming (distortions in the animal’s flow field) (Fig. 4). The pattern of cranial lateral line canals is similar for all chimaeroids, but its overall

**Chondrichthyes Sensory Systems, Fig. 4** Lateral view of a small-spotted catshark *Scyliorhinus canicula* (left) and ventral view of an eyespot skate *Atlantoraja cyclophora* (right), showing the pattern of lateral line canals and pores

and ampullary organs. The upper detail highlights neuromasts' positions inside lateral line canals, and the bottom detail shows ampullary organs at skin surface

unique pattern is poorly understood and difficult to homologize (entry ► [“Homology”](#)) with other vertebrates (Didier 1995).

Nonpored canals are isolated from the environment and do not respond to pressure differences. Instead, these canals may function as tactile receptors that receive information on contact with prey, the substrate, or conspecifics during social interactions (Maruska 2001; Gardiner et al. 2012). Nonpored canals are found on the ventral surface of skates and rays, and also on the head of many shark species.

Spiracular organs and vesicles of Savi are specialized mechanoreceptors isolated from the surrounding water, mainly found in rays and with some function in proprioception and tactile stimulation, respectively. However, little is known about their biological function (Maruska 2001).

The lateral line system detects differential movement between the body surface and the surrounding water. Even in low-visibility waters or during nocturnal activities, chondrichthyans can navigate around obstacles (a kind of distant touch) in their environment by detecting compression

waves in the water through lateral line system (Kardong 2016). Changes in the shape of cupula are coupled to stereocilia and kinocilia motions, causing depolarization or hyperpolarization of the hair cell. Then, the information is sent to the mechanosensory-processing centers in the hind-brain through the primary afferent neurons (Gardiner et al. 2012). There is some evidence that the mechanosensory lateral line system could play a secondary role in hearing since low-frequency vibrations result from sounds propagating through the water, in a similar way that stimuli is detected by neuromasts (Montgomery et al. 2009; Kardong 2016).

#### Membranous Labyrinth

The membranous labyrinth originates from the lateral line system and contains **three semicircular canals** filled with **endolymph** and surrounded by **perilymph**, both liquids presenting a similar consistency to the lymph (Kardong 2016). In chondrichthyans, the membranous labyrinth is connected with the environment through the **endolymphatic duct**. Three sensory areas

connected and involved in balance and sound perception are present along the semicircular canals: the **saccul**, **lagna**, and **utricle** (Fig. 5). Besides these compartments, expanded neuromasts known as **cristae** are arranged in ampullae at the base of each semicircular canal. All these components are encapsulated within the optical region (situated at the posterior end of the chondrocranium) (Hueter et al. 2004; Kardong 2016).

The sensory receptor inside the saccul and utricle is the **macula**, which is a modified neuromast with hair cells and a gelatinous cupula overlain by an otoconial mass (Gardiner et al. 2012). Head movements or changes in body position modify the orientation of maculae, and the otoconia (calcium carbonate granules) interact with the maculae, accentuating the response to angular acceleration or changes in head orientation. Semicircular canals respond to rotation and angular acceleration by differences in responsiveness of the canals and liquids within these regarding the head movements (Kardong 2016).

#### Auditory System

The hearing has different aspects when comparing aquatic and terrestrial vertebrates. The air and inner ear liquids differ regarding their responsiveness to sound waves. The evolution of medium ear and associated structures in terrestrial vertebrates

collects, amplifies, and transmits sounds from the air to the inner ear at a level sufficient to stimulate the sensory hair cells. On the other hand, in aquatic environments, both the vertebrates and their environment are composed mainly by water; in a way, both present similar frequency ranges. Thus, the sound propagates easily from the aquatic environment to the liquid inner ear environment (Gardiner et al. 2012).

The **saccul** and **lagna** (developed as an extension of the saccul) are both involved in the hearing. Hair cells located within the saccul and lagna are stimulated by sound vibrations and move against otoconia of different shapes and sizes. Otoconia are sensible to accelerations produced by a sound field and play a similar role to the otolith organs of bony fishes helping to localize a sound source. Sound information differing in direction and frequency are detected by the hair cells and transmitted to the hind brain via the VIII (octaval) cranial nerve (Gardiner et al. 2012).

A tympanic connection to the posterior semicircular canal called **fenestra ovalis** is located at the base of the parietal fossa (posterior end of the skull), which consists of a unique condition of chondrichthyans. The posterior canal ducts of the semicircular canals contain a sensory macula, the **macula neglecta**, which is not overlain by otoconia. The macula neglecta consists of one or

#### Chondrichthyes Sensory Systems,

**Fig. 5** Generalized chondrichthyan inner ear, based on Hueter et al. (2004) and Kardong (2016)

two patches of sensory hair cells that show a variety of orientations. The variation in the structure of the macula neglecta has been hypothesized to be linked to the foraging behavior (Corwin 1978), and several studies have shown the importance of the macula in detecting sound and/or vibration (Lowenstein and Roberts 1951).

Despite the auditory system being better described in elasmobranchs, some differences have been reported for chimaeras' auditory system. In the last, there are differences in position, elaboration, and enlargement of the macula neglecta, presence of a connection (*crus commune*) between the anterior and posterior semicircular canals, and absence of separation between saccule and utricle (Maisey 2001). However, the functional significance of these variations is not yet understood.

### Electroreception

Electroreception is the detection of external electric fields by specialized receptor cells that convert electric currents into action potentials (Crampton 2019). It evolved several times in Vertebrates' history but is usually found in fishes, some amphibians tadpoles, and living monotremates, albeit elasmobranchs being one of the better-known groups to use this sense.

The electroreception can be discriminated in two types: passive electroreception, the capacity of detecting weak, direct current fields or low-frequency sinusoidal fields (usually <30 Hz); and active electroreception, the capacity of the organism to generate an electric field by their electric organ discharges, and to perceive the environment by the distortions of this field caused by objects and organisms (Caputi et al. 2008; Crampton 2019).

Electroreceptors (entry ► [“Electroreceptors”](#)) are **modified neuromast organs** located in pits within the skin, predominant at the anterior region of the body, and can be divided into two types: ampullary organs and tuberous organs. They usually develop from placodal tissue adjacent to the tissue that forms the lateral line mechanoreceptors; meanwhile, ampullary organs are specialized in detecting weak electric currents, and tuberous organs are specialized in responding to

high-frequency electric fields. Only passive electroreception is present in chondrichthyans, which present **modified ampullary organs**.

### Ampullary Organs

All chondrichthyans possess an elaborate ampullary electroreceptor system that is exquisitely sensitive to low-frequency electric stimuli (Hueter et al. 2004). Besides many living gnathostomes having ampullary organs, in elasmobranchs such organs are clustered on the head, adjacent to the lateral line canals, and are frequently referred to as **ampullae of Lorenzini** (Fig. 6). Chimaeroids are known to have electroreceptive ampullae that are homologous to the ampullae of Lorenzini of elasmobranchs, despite the ampullae pores of the first being usually smaller and in lesser amounts than those of the second (Lisney 2010).

The ampullary system of chondrichthyans is known to mediate orientation regarding local

**Chondrichthyes Sensory Systems, Fig. 6** Chondrichthyan ampullary organ (also known as ampullae of Lorenzini), showing the sensory receptor cells, supporting cells, and mucopolysaccharide-filled ampullary canal. The major extension of the ampullary organ lies beneath the epidermis, in the dermis

inanimate electric fields, in the detection of bioelectric fields produced by preys and predators, and also might participate in geomagnetic navigation and intraspecific social interactions (see Hueter et al. 2004 and Lisney 2010 for a compilation). Besides electroreception, the ampullary organs can participate in temperature sensitivity, which is translated into electrical information (Brown 2003).

A single ampulla consists of a small chamber and a subdermal canal that projects to the surface of the skin (Fig. 6). The ampulla chamber is formed by several small pouches, the alveoli, which present the sensory receptors and support cells aligned at its wall. The support cells also produce a glycoproteic gel that acts as an electric conductor from the ampulla pore to its sensory receptors (Hueter et al. 2004).

The ampullary organs form clusters, especially at the head of sharks and chimeras, with additional pores along the body of rays (Fig. 4). The highest density of ampullary organs is found near the mouth, being related to prey detection (Kajiura et al. 2010; Newton et al. 2019). The extended snouts of some chimaerids and elasmobranchs offer an opportunity to increase the spatial distribution of ampullary electroreceptors, with ampullary pore density relatively higher at the ventral surface of the head (Lisney 2010).

There is substantial interspecific variation in the number and distribution of ampullary organs, which might have a relation to phylogenetic relatedness, morphological similarity, species distribution within and across habitats, and diet preferences (Kempster et al. 2012). Because individuals do not grow new pores or redistribute them during development, the electrosensory resolution decreases as the inter-pore distance increases throughout ontogeny (Kajiura 2001). Therefore, as chondrichthyans age, they will experience a net loss of electroreceptive resolution, a gain in receptor sensitivity, and a larger sensory field that samples a greater water volume (Newton et al. 2019). Nevertheless, for chondrichthyans as a whole, the region of electroreception information integration (anterior and posterior lateral line lobes at the telencephalon) is usually enlarged, suggesting that electroreception (besides vision and lateral line

information) may be of importance for Chondrichthyes' sensory system (Lisney 2010).

## Chorion

Bhabotosh Barman

Department of Zoology, Banaras Hindu University, Varanasi, India

Chorion is the thin extraembryonic membrane that covers the embryos and other extraembryonic membranes of reptiles, birds, and mammals. The extraembryonic membrane is made up of certain specialized embryonic tissue or structures that

temporarily or permanently do not enter into the formation of the embryo themselves but plays an important role to fulfil the care and maintenance of the developing embryo. In the embryos of all terrestrial vertebrates, four sets of extraembryonic membranes are common, these are: amnion, chorion, yolk sac, and allantois. Out of these, chorion is the outermost one.

## Development

In developing reptiles, birds, and mammals, the lateral plate mesoderm splits into an outer somatic layer of mesoderm and an inner splanchnic layer of mesoderm. The somatic layer lies at the inner side of the ectoderm and the splanchnic layer lies at the outer side of the endodermal layer. There is also a coelomic space which is present between these two mesodermal layers. The somatic layer of mesoderm and ectoderm are collectively known as somatopleure, while the splanchnic layer of mesoderm along with endoderm forms the splanchnopleure. This extraembryonic somatopleure contributes to the formation of chorion and amnion while the splanchnopleure forms the yolk sac and allantois (Gilbert et al. 2003) (Fig. 1).

## Structure

Chorion is made up of two layers: trophoblast as the outer layer and mesoderm as the inner layer.

**Chorion, Fig. 1** Diagrammatic representation of extra-embryonic membranes

The trophoblast is made up of cytotrophoblast and syncytiotrophoblast. The cytotrophoblast is the inner one and considered to be the trophoblastic stem cells. The syncytiotrophoblast is the outer layer and made up of multinucleated type of cells (Cruz et al. 1991; Bianchi et al. 1993). In mammals, both the cytotrophoblast and syncytiotrophoblast initially helps the embryo to adhere and move into the uterine wall by digesting uterine tissue. At the same time, the uterus send blood vessels into this area and the extraembryonic mesoderm from gastrulating embryo extend outwards. This extraembryonic mesoderm then joins the trophoblastic extension and gives rise to the vessels of the umbilical cord. This fully developed extraembryonic chorion in mammals fuses with the endometrium of the female uterus to create the placenta (Renfree et al. 1982).

In reptiles and birds, the mesodermal layer of chorion fuses with the adjacent mesodermal layer of the allantois and formed chorioallantois or chorioallantoic membrane. This vascular membrane composes of three different layers: chorionic epithelium, the mesenchyme, and the allantoic epithelium (Fig. 2).

## Function

Development of extraembryonic membrane in reptile, bird, and mammal's embryos has taken a new evolutionary direction. Egg developing in water provides the egg with various favorable environmental conditions; however, none of the favorable features are provided on dry land. Reptiles and birds lay their eggs on dry land. Thus the eggs are subjected to desiccation and sudden change in temperature. To accomplish this, the embryo produces extraembryonic membranes to mediate with the environment. Although in mammals instead of shell placenta is present, but the basic pattern of extraembryonic membrane remain same.

Thus chorion, as the outermost extraembryonic membrane serves the following functions.

- (i) In the embryo of birds and reptiles, the blood capillaries are found between chorionic epithelial cells which closely adhere to the shell.

**Chorion,****Fig. 2** Diagrammatic representation of chorionic layers

This allows maintaining a close contact with the air present in the pores of the shell membrane. As a result, exchange of oxygen and carbon dioxide gases happen in the developing embryos.

- (ii) In birds during embryonic development, chorioallantoic membrane helps in transporting calcium into the embryos from the eggshell, thus it plays an essential role in bone formation.
- (iii) In mammals, the chorion forms the fetal portion of the placenta. Through this placenta mother provides the fetus with nutrients and oxygen, and the fetus sends its waste products (mainly carbon dioxide and urea) into the maternal circulation (Schjenken et al. 2012).
- (iv) The chorionic villi do not allow the mixing of maternal and fetal blood cells, thus it provides barriers to both the mother's and fetal immune system (Gilbert et al. 2003).
- (v) Placenta also provides hormones for the maintenance of pregnancy.
- (vi) Recent studies also suggest some placental mechanisms that block the mother's immune system from attacking foreign substances produced by the embryo (Schjenken et al. 2012).

## Definition

The non-random distribution of acoustic signals where multiple individuals signal in close temporal and spatial proximity.

## Introduction

Choruses are a phenomenon produced by diverse taxa, including birds, mammals, and

fish. Moreover, chorusing behavior is particularly prevalent in anurans and insects. During chorusing behavior, there is a substantial peak in acoustic signal production including increases in signal rate, signal diversity, and signal complexity. Chorusing, in many species, may be the by-product of male-male interactions (Rehberg-Besler et al. 2016). The acoustic signals produced during chorusing exhibit species-specific features, which may be temporal (e.g., call or song rates) or spectral (e.g., patterns of frequency modulation within a signal). Many species exhibit distinct diel patterns in the production of choruses. For example, dawn chorus behavior has been described in diverse taxa, including birds, mammals, and fish, where signal production peaks during the period immediately before sunrise (Burt and Vehrencamp 2005). The signals that make up an animal chorus are produced to serve multiple biological functions, including social bonding, territory defense, and mate attraction (Ryan et al. 1981; Burt and Vehrencamp 2005). Further, the many biological functions of chorusing are not mutually-exclusive. Despite the benefits of chorusing, however, there are risks associated with broadcasting signals through the environment, including energy expenditure and risks of predation.

## Biological Functions

Chorusing, and the associated increase in signal production, may serve multiple biological functions, including social bonding, territory defense, and mate attraction. Acoustic communication is an efficient method of signaling commitment and affiliation (Hall 2009). In many taxa, chorusing may serve an important role in social bonding between mates or between social groups (Hall 2009). The males of many species use acoustic signals to establish and defend territories and resources. In insects, the acoustic signals of males can attract and repel rival males, which facilitates the establishment of evenly distributed territories among conspecific animals (Robinson and Hall 2002). Many birds will alter their dawn chorus behavior in response to a male competitor

intruding its territory (Foote et al. 2011). In response to an intrusion by a male competitor during chorusing, the male may attack, alter signal production to challenge the intruder, or abandon the territory. In addition to territory and resource defense, the acoustic signals of choruses are produced to attract potential mates. Males of many species will advertise acoustically from locations throughout established territories that are optimal for signal transmission. In many insects and anurans, males will aggregate near resources (e.g., vernal ponds) and engage in chorusing to attract mates. In many chorusing species, females can be exposed to acoustic signals produced by multiple neighboring males. As a result, females of many chorusing species are capable of discerning and comparing the advertisement signals of potential mates and will often select higher-quality mates (Richardson et al. 2008).

## Benefits and Costs

Individuals may gain multiple benefits from participating in choruses. In aggregating species of anurans and insects, males participating in aggregations can have advantages over lone calling males (Ryan et al. 1981). Choruses with more signalers are louder in amplitude and can attract females from wider geographic areas (Ryan et al. 1981). In many taxa, such as songbirds, chorusing and the associated maximum acoustic output is associated with the time of day when atmospheric conditions are most optimal for acoustic communication in order to increase signal transmission. Despite chorusing during optimal times of day, there are energetic costs associated with the production and maintenance of complex acoustic signals. Further, while animals are occupied with increased signal production and complexity, they are not dedicating time to foraging. The acoustic signals broadcast during chorusing can be used to advertise the signaler's location to potential mates; however, many predators are also able to acoustically detect an individual's location through eavesdropping on these signals (Lang et al. 2005).

## Conclusion

Chorusing, the non-random production of acoustic signals by multiple individuals, is a widespread phenomenon exhibited by diverse taxa, including birds, mammals, fish, insects, and anurans. There are numerous non-mutually exclusive biological functions that chorusing may serve including social bonding, territory defense, and mate attraction. Although there are multiple benefits gained from chorusing, the broadcasting of acoustic signals carries risks, including increased predation.

## Chris Evans

Linda Evans

Macquarie University, Sydney, NSW, Australia

Christopher Stuart Evans was born in Cambridge, England, on May 25, 1959. In 1968, his family emigrated to the United States but within 2 years moved again, this time to The Netherlands. Upon returning to the United States in 1973, Chris chose to attend a prep school in the United Kingdom and so completed his secondary education at Malvern College in Worcestershire. Returning to England helped Chris to fulfil an ambition that he had nurtured since a child, which was to attend Cambridge University, as this was also his father's alma mater. After qualifying in 1977, it was at Cambridge that he subsequently discovered his vocation. Pivotal during his studies in natural sciences was his first biological experiment on the display behavior of Siamese fighting fish (Evans 1985), which not only cemented his growing interest in ethology but in animal communication, in particular.

Upon completing his bachelor's degree in 1980 and returning to his family's home in the United States, a chance visit to Washington University in St. Louis seeking summer employment instead led to the offer of a place in their PhD program in experimental psychology, which Chris commenced later that year. Under the supervision of Stephen Gaioni, he embarked on a study of mallard duckling vocalizations, devising a series of behavioral experiments that used a computerized system, the latter triggering a love of innovative technology that was to be a significant feature of his later research.

The opportunity to work with animal behaviorist Peter Marler, then in the department of behavioral sciences at Rockefeller University, saw Chris with wife (and later research assistant) Linda relocate to the Center for Field Research in Ethology and Ecology in Millbrook, New York, just prior to his graduation in late 1986. Upon the award of a three-year NIMH postdoctoral fellowship, his new line of comparative research focused on categorical

perception and referential communication, specifically the production and perception of complex acoustic signals in domestic fowl. This experience deepened Chris' knowledge of digital signal processing techniques to analyze and manipulate biological sounds and also led to his first experiments using computerized visual stimuli to elicit alarm calling in birds. Progress was interrupted, however, when in mid-1989 the Marler Lab moved to the University of California at Davis, where they joined the department of zoology (later physiology and behavior). Chris played an instrumental role in the translocation and re-establishment of the lab's 20 tons of equipment, including the successful shipment of his beloved chicken colony, an experience that both highlighted and honed his exceptional organizational skills. Work carried out at the UC Davis Animal Communication Lab included his pioneering experiments using video to elicit behavioral responses (e.g., Evans and Marler 1991) and the first demonstration of referential signaling in a non-primate species (Evans et al. 1993).

In 1993, Chris accepted a lectureship in the department of psychology at Macquarie University in Sydney, Australia. Building his lab with limited resources was challenging, but he applied himself to the task with energy and determination. Initially based in a 1940s era cottage on the Macquarie grounds, he gradually expanded the operation to include extensive aviaries for his new chicken colony and adjacent transportable buildings to house indoor birds and extra office and lab space. Soon after arriving at Macquarie, he was awarded his first major federal funding from the Australian Research Council, and this, along with many subsequent grants, allowed regular investment thereafter in new digital imaging technology to support his ever-evolving, innovative exploration of animal cognition (e.g., later use of 3D animations and animatronics). He struggled initially with the distance that now separated him from his former US colleagues (whom he affectionately referred to as his "tribe"), and so, he made it a priority to attend the annual conference of the Animal Behavior Society, where his quick wit and eloquence became legendary. He also

found new research partners in the local Australasian Society for the Study of Animal Behaviour, for which he was later elected president (2000–2001).

Chris's lab grew steadily with the addition of graduate students and postdocs (e.g., Dan Blumstein, Ann Göth, and Ximena Nelson) and so did the range of topics and species studied, which was to eventually include courtship behavior by swordtail fish (Rosenthal and Evans 1998), signaling behavior by Australian lizards (Ord et al. 2001), social learning in brush turkeys (Göth and Evans 2004), and the antipredator behavior of wallabies (Griffin et al. 2001) – although Chris' primary research interest continued to be referential signaling using domestic fowl as a model system (e.g., Macedonia and Evans 1993; Evans 1997). Indeed, his work in extending understanding of functionally referential signals is acknowledged by researchers today as a major contribution to the fields of animal vocal communication and language evolution.

The arrival of behavioral biologists Ken Cheng in 1995 and Phil Taylor in 2002, in whom he found like-minded visionary colleagues, provided a catalyst for Chris's expansion of animal studies at Macquarie, first with the establishment of the *Center for the Integrative Study of Animal Behavior* (CISAB) in 2005 and in 2007, when animal behavior was identified by the university as a *Centre of Research Excellence* (CORE). The latter led to increased financial investment and support by Macquarie, enabling Chris as director of the CORE to not only headhunt new scientists (behavioral ecologists Simon Griffith and Martin Whiting and neuroethologist Andrew Barron) but also enlarge the facilities for animal behavior research, resulting in the construction of a purpose-built laboratory building on the campus to house the new teams. By 2009, CISAB had attracted 25 PhD students and 11 postdocs and that year alone received over one million dollars in grant funding, with national and international collaborative projects that included links with industry.

Chris's vision for the future was cut short, however, when in mid-2008, after experiencing occasional weakness in his legs, he was diagnosed

with motor neuron disease (also known as ALS or Lou Gehrig's disease). Despite the bleak prognosis, he continued to apply his energies to further consolidating research in animal behavior and cognition at Macquarie and in 2009 was instrumental in founding a new department of brain, behavior, and evolution. Although soon confined to a wheelchair, he continued to plan future work and also publish extensively in partnership with his former PhD student, now postdoc, K-lynn Smith (e.g., Smith and Evans 2011), with whom he was awarded a prestigious Australian Museum Eureka Prize in 2010 for "Scientific Research that Contributes to Animal Protection." However, the awards of which he was most proud were those bestowed by his "tribe": first, his election as a fellow of the Animal Behavior Society in 2004 and then distinguished animal behaviorist in 2010. Chris Evans died on November 17, 2011, but is remembered as a leader and technological innovator in the study of animal communication.

## Christine Ladd-Franklin

Roger K. Thomas

Department of Psychology, University of Georgia, Athens, GA, USA

Christine Ladd (1865) Student at Vassar College. (Photo Courtesy of Rare Book and Manuscript Library, Columbia University)

## Introduction

Christine Ladd (1847–1930) was born in Windsor, Connecticut. Her mother died when Ladd was 12, but she received encouragement and support from her father and grandmother to receive education through high school.

Desiring to attend college, Ladd sought her grandmother's support in recruiting her father's assistance. Her grandmother objected that, after 4 years of college she would be too old to get married. Ladd replied that, although it would give her "great pleasure to entangle a husband," it was unlikely because of the females in New

England greatly outnumbered males (this was one year after the end of the American Civil War) and that she “was decidedly *not* handsome.” Therefore, she argued that if she needed to support herself, she needed a college education. Her grandmother acquiesced and, in the Fall of 1866, she enrolled at Vassar College (Furumoto 1992, p. 178).

At Vassar, Ladd reported that she devoted most of her time to astronomy under the influence of Maria Mitchell, whom Rossiter (1982, p. 12) described as “the most important woman scientist in America in the nineteenth century.” Rossiter’s opinion was supported by the following:

In 1847 Maria Mitchell not only calculated the position of a new comet but also observed it across the sky and thereby won (after some controversy) the gold medal that the king of Denmark had promised to the discoverer. This made the twenty-eight-year old a celebrity. She was soon elected the first woman member of the American Academy of Arts and Sciences ... the American Association for the advancement of Science ... and eventually (1869) one of the first American women in the American Philosophical Society of Philadelphia.

After graduation from Vassar, Ladd taught for several years at secondary schools for women, an occupation she did not enjoy.

Eventually (1882), Ladd would attend and complete the requirements for a Ph.D. in mathematics and logic at Johns Hopkins University. However, as Johns Hopkins did not officially enroll female students, she was only able to attend with the support of Mathematics Professor, James J. Sylvester, who had been impressed by Ladd’s published papers in mathematics. Ladd studied mathematics with Sylvester and logic with Charles S. Pierce which made her the first American woman to study mathematics and logic at the graduate level (Aglar and Durmus 2013). While at Johns Hopkins, Ladd married Fabian Franklin who earned his Ph.D. degree in mathematics there in 1880. Ladd-Franklin completed her Ph.D. requirements in 1882, but she did not receive the degree until 1926, occasioned somewhat by Johns Hopkins’ 50th Anniversary. At age 79, and 44 years after earning her degree, she attended the ceremony to receive it (Rossiter 1982).

Some of the most recognized historians who have written about aspects of Ladd-Franklin’s life (e.g., Furumoto 1992; Rossiter 1982; Scarborough and Furumoto 1987) have tended to emphasize Ladd-Franklin’s hard-fought career and efforts to gain recognition for women scientists and, at length, her conflict with Edward Bradford Titchener (more below), and they tended to write less about Ladd’s contributions to mathematics, logic, and psychology. This entry will include some information about Ladd-Franklin’s hard-fought career, but it will also include information about some of her contributions as a psychologist and logician.

## **Trials and Tribulations**

Among her trials and tribulations, Ladd-Franklin never had the equivalent of a tenured or tenure-track academic position, although she taught (often without pay) at Johns Hopkins and other universities, perhaps, most notably Columbia University. Fabian Franklin, by then professor of mathematics at Johns Hopkins, resigned in 1895 to become editor of the *Baltimore News*. In 1908, he became associate editor of the *New York Evening News* (Furumoto 1992) which is why Ladd-Franklin affiliated with Columbia. Most of Ladd-Franklin’s university-level positions were in psychology departments, because after she developed the Ladd-Franklin theory of color vision, she mostly self-identified as a psychologist. She also continued to teach and publish in logic throughout her career.

## **The Society of Experimentalists: Ladd-Franklin Versus Titchener**

Edward B. Titchener (1857–1927) was a founding member (1892) of the American Psychological Association (APA). By 1904, he became dissatisfied by too few presentations at APA of “pure” experimental psychology as he defined it, so Titchener resigned from APA and organized what eventually became the Society of Experimentalists. Titchener insisted on excluding

women from its membership and from attendance at its meetings. His primary reasons were that the presence of women would inhibit frank discussions and would interfere with the men's enjoyment of smoking. Ladd-Franklin's conflict with Titchener is discussed extensively in Rossiter (1982), Scarborough and Furumoto (1987), and Proctor and Evans (2014).

### Who Was Titchener?

Titchener, a native of England, earned an A.B. degree (1890) from Oxford University specializing in evolutionary biology, and he stayed an extra year to study with the eminent physiologist, John Burden-Sanderson. He then earned a Ph.D. (1892) in Psychology with Wilhelm Wundt, the widely recognized founder of experimental psychology. Titchener came to Cornell University in 1892 where he remained until his death in 1927 (Boring 1950).

### Women and the Society of Experimentalists

Many women psychologists confronted Titchener about his barring women from the Society of Experimentalists. Perhaps, Ladd-Franklin's most dramatic encounter with Titchener occurred in 1914 when the Society was to meet at Columbia University, where Ladd-Franklin was teaching, and a topic to be discussed was color vision about which she was a world authority. Seeking permission to attend, she wrote a fiery letter that included the following:

Is this good time for you to hold the mediaeval attitude of not admitting me to your coming psychological conference ... at my very door? So unconscientious, so immoral – worse than that – so unscientific!

...Both the Psychological and Philosophical Associations have long admitted women to their smokers and everything (I smoke – I should be very unfashionable if I didn't ...). It is only this acute-thinking and discussing little organization of yours (which seems to be so sadly dominated by you!) which still holds out. So mediaeval! – such an indignity! – well meant, I know – you have told me so – but such a mistaken kindness! Do quickly repent! And you need me! (Rossiter 1982, p. 280)

Titchener did not repent, and Ladd-Franklin asked James McKeen Cattell, the meeting's Columbia host, to take her as his guest, which he did. The

members, apparently begrudgingly, allowed her to attend the discussions on color vision.

After Titchener's death, Margaret Washburn and other women were admitted, but Ladd-Franklin was never invited to join.

Proctor and Evans (2014) defended Titchener against charges of misogyny. Among their points, Titchener supervised the Ph.D. degrees of 21 women, including Margaret Washburn, America's first woman to earn a Ph.D. in Psychology (1894). Titchener also supervised the Ph.B. (Bachelor of Philosophy, 1896) of Celestia S., Parrish who may be best remembered for establishing the first psychological laboratory in the southern United States, which she did at Randolph-Macon Woman's College in Lynchburg, VA (Thomas 2006). Washburn in 1927 expressed her long-term dislike for Titchener (see Scarborough and Furumoto 1987, p. 128), but in 1925 Parrish wrote that he gave her "... the most generous assistance then [referring to his role in her earning her degree] and afterwards became my very kind friend" (see Thomas 2006, p. 28).

### Ladd-Franklin's Accomplishments in Logic

Ladd-Franklin's dissertation supervisor was Charles S. Pierce. Historically, Pierce was, perhaps, America's most important logician (Putnam 1982). Ladd-Franklin's dissertation, *On the logic of algebra*, was published in *Studies in logic by members of the Johns Hopkins University* that was edited by Pierce (Agler and Durmus 2013). Agler and Durmus (2013, p. 306) wrote:

...Ladd-Franklin was not simply a pupil of Pierce, she was also his friend, managing editor, and as Shea Zellweger (1997, p. 336) writes "as much Pierce's mentor as she was his student."

*Time Magazine* in 1926 recognized that Johns Hopkins had that year awarded Ladd-Franklin's Ph.D. degree, 44 years late. About Ladd-Franklin it was written:

She completed her studies with distinction, demonstrating a form of rebuttal in argument called anti-logism, which has been recognized as "the

crowning achievement in a field [logic] worked over since the days of Aristotle” (*Time*, Vol.7 Issue 9, p. 30).

At age 81, Ladd-Franklin (1928, p. 532) reported:

I take it very ill of Mr. W. E. Johnson that he has robbed me without acknowledgement, of my beautiful word, “antilogism”. He says “Correlative to the syllogism we may here introduce the antilogism” (p. 75, Vol. II. Of his *Logic*), without any reference to the fact that the antilogism is the basic feature of my theory of deductive reasoning. (see Eugene Shen in *MIND*, pp. 54–60, 1927)

She continued by, once again, defining and illustrating the use of the antilogism. The antilogism is not easily explained, but perhaps a few quotations from Ladd-Franklin (1928, p. 532) will help.

This is, in fact, the natural form of reasoning ... invented before the more abstract and remote syllogism. I give at once an example of it – a real occurrence. A little girl of four years ... was making ... the experiment of eating her soup with a fork. Her nurse said to her, “Nobody eats soup with a fork, Emily,” and Emily immediately replied “But I do, and I am somebody.” (The connecting logic-word in the case of the antilogism is *but* instead of *therefore, so, or consequently*.) This instance (which may be taken as typical) is enough to show that the antilogism is quite as easy and as natural (in the proper circumstances) as any other form of deductive reasoning.

The interested reader is encouraged to read this entire two-page account of the antilogism as well as seek her many other contributions to logic.

## Ladd-Franklin's Accomplishments in Vision and Color Vision

On this topic, Ladd-Franklin is best known for 24 of her publications ranging from 1892 to 1926 that she compiled at age 82 for her book, *Colour and Colour Theories* (1929); the 24 publications are listed on page 281.

Before Ladd-Franklin, the two dominant theories of color vision were the Young-Helmholtz trichromatic theory and Hering's opponent process theory. Helmholtz updated Young's (1802) theory by using the latest information from physics and physiology. Hering drew from physiology but also from psychological

experiments using humans. Accompanying her husband, Fabian, on his sabbatical to Germany in 1891, Ladd-Franklin visited Helmholtz and Hering and worked in the laboratories of Helmholtz's protégé, Arthur König, and Hering's protégé, G. E. Müller. According to Kargon (2014), Ladd-Franklin added two new disciplines to her approach to color vision: evolutionary biology and symbolic logic.

Ladd-Franklin sought to reconcile the differences and deficiencies of the trichromatic and opponent process theories. The quoted summary below of her theory was based on her in-depth knowledge evident in Part I of her book of the evolution of color vision, the anatomy and physiology of the retina, the physics of light, and psychological research. Her knowledge of the various forms of color blindness also contributed to her theory of the evolution of color vision.

...there is a light sensitive substance in the rods which gives off, under the influence of light, a reaction-product which is the basis of the primitive sensation of whiteness. In the cones the next higher stage of development of the colour-sense (the yellow and blue vision of bees, that of partially chroma-blind individuals and of our own mid-periphery), the same light-sensitive substance has become, by a simpler molecular rearrangement, more specific in its response to light ... such ... that the two ends of the spectrum act separately to produce nerve excitant substances which ... when ... produced both at once, unite chemically to form the “white” nerve-excitant out of which they were developed. In the third and final stage the “yellow” nerve-excitant has again undergone a development in the direction of greater specificity, and red and green vision are acquired. (Ladd-Franklin 1929, p. 161).

## Closing Remarks

Ladd-Franklin's first publication on color vision was in the *Proceedings of the International Congress of Experimental Psychology, London* (1892) and was based on her oral presentation at the 1892 meeting. She critiqued deficiencies in Helmholtz's trichromatic theory and Hering's opponent process theory. Helmholtz was present. Overhead later that evening criticizing one of the

presentations (not Ladd-Franklin's), Helmholtz was asked what he thought of Ladd-Franklin's presentation. Helmholtz replied (English translation), *Oh, Mrs. Franklin, she understands the matter* (Ladd-Franklin 1929, p. 148). "She understands the matter" would have been an appropriate epitaph for Ladd-Franklin.

## Definition

The two individual chromosomes attached together at centromere in a newly replicated chromosome are known as chromatids. They are clearly visible as two diagonal arms of a typical X-shaped chromosome in metaphase.

## Introduction

The cell, during DNA replication or synthetic (S) phase of the cell cycle, duplicates each chromosome, giving rise to chromatids containing equally divided genetic material. These duplicated chromosomes or chromatids are then separated equally with the help of microtubules to the two newly formed daughter cells (Fig. 1). The two chromatids of the same chromosome are referred as sister chromatids, while the chromatids of homologous chromosomes are termed as non-sister chromatids (Fig. 2).

## Homologous Chromosomes vs. Sister Chromatids

Diploid organisms like humans have two sets of individual chromosome, each of which is inherited from the maternal and the paternal gamete. These sets of chromosomes are known as homologous chromosomes (homologs) (Fig. 2). Although homologs are copies of the same chromosome inherited from two different parents, they are not identical as they might have different alleles for same genes, while the sister chromatids

# Chromatid,

**Fig. 1** Simplified dynamics of chromatids during cell division

**Chromatid, Fig. 2** The picture describes differences among homologous and nonhomologous chromosomes (a) and sister vs. non-sister chromatids (b)

are the replicated form of an individual chromosome, and hence they are identical to each other. Chromatids of two homologous chromosomes are called non-sister chromatids, and like homologous chromosomes, they carry the same genes but are not identical to each other.

## Chromatids Are Visible in Mitotic Phases

Though chromatids are synthesized in synthetic phase (S-phase) of the cell cycle, they are not

visible until metaphase. During prophase, the chromatids are still attached together throughout their length making it impossible to visualize them separately (Figs. 3 and 4a, b). During this stage, ring-shaped protein complexes, *cohesin I and II*, encircle the two chromatids holding them together like in a “handcuff.” Cohesin complex consists of multiple proteins including *SMC I and III* (structural maintenance of chromosome), *RAD21*, *RAD21L*, *REC8*, and *STAG* proteins (Brooker and Berkowitz 2014). Cohesins at the arms are degraded as soon as cells enter into mitotic phase (M-phase), and chromatids are

**Chromatid,**

**Fig. 3** Pictorial demonstration of chromatids arrangement into mitotic phases; during metaphase all the chromosomes come at one axis, and the two chromatids are then pulled away toward opposite pole in anaphase

**Chromatid, Fig. 4** Chromosomal spreads from human peripheral blood lymphocytes representing morphology of chromosomes/chromatids at different mitotic phases of cell division. Prophase with indistinct chromatids and entangled chromosomes (**a**), late prophase/early

metaphase with partly resolved chromatids (**b**), late metaphase having chromatid arms totally separate; however they still have centromeric connection (**c**), and completely separated chromatids at anaphase (**d**)

visible separately in metaphase but are still attached together at the centromere. The appearance of chromosomes with two chromatids in metaphase is now visualized as classical X-shaped form (Figs. 3 and 4c). At anaphase protein complex called as *APC* (anaphase-promoting complex) releases *cohesin complexes* at the centromere through an enzyme *separase* (Peters 2006). Hence, with the start of anaphase, the chromatids are free to be pulled away from the centromere toward opposite poles and become separate chromosomes (Figs. 3 and 4d).

### Chromatids Play Essential Roles in DNA Repair

As described earlier, sister chromatids have identical sequence and hence provide opportunity for an essential cellular activity, i.e., DNA repair. DNA double-strand breaks (DSBs) are the most lethal type of DNA damage for a cell. They may lead to cell death or transformations through multiple kinds of chromosomal aberrations such as deletions, translocations, fragmentations,

etc. Therefore, to protect from these damages, cells are provided with extensive DNA repair mechanisms. Homologous recombination is the most accurate mechanism for DSB repair. In this repair mechanism, the genetic information lost due to DSB is restored using identical information from the sister chromatid as a template (**sister chromatid exchange**, Fig. 5) (Renkawitz et al. 2014; Goldfarb and Lichten 2010). Although sister chromatid-based HR is the predominant repair mechanism (Kadyk and Hartwel 1992), in rare instances when sister chromatids are not available, HR pathway may also use non-sister chromatids as template to recover lost information (Lafave and Sekelsky 2009).

In cases of nonavailability of sister chromatids, i.e., in pre-S-phase, sister chromatid exchange-based HR cannot take place. In such scenario, DNA repair does not necessarily involve homology and joins nearby broken ends of strands together. There are probabilities that wrong ends get joined leading to chromosome or chromatid-type aberrations. This mechanism is known as **nonhomologous end joining (NHEJ)** which is highly error prone.

**Chromatid, Fig. 5** DNA repair through homologous recombination pathway using sister chromatid exchange. Damaged part of one chromatid is resynthesized using undamaged sister chromatid as template. Sister chromatid exchange does not create recombinants as both the chromatids are identical

## Role of Chromatids in Genetic Diversity

Homology between non-sister chromatids is responsible for an important phenomenon in biological system, i.e., genetic diversity (Hunter 2015). Crossing over is a process of exchange of sequences between maternal and paternal chromosomes during meiosis and hence creating crossover/hybrid chromosomes in the gametes (Fig. 6). The process includes pairing of the two chromatids at homologous regions followed by breaking and rejoining of segments. Recombination of non-sister chromatids creates new combination of genetic material and hence diversity among genomes. Genetic diversity created during crossing over is the key reason why siblings are not identical as they receive different combination of genes. In contrast, identical twins which result from splitting of same fertilized eggs during gestation carry identical genome.

## Chromatid Aberrations Indicate DNA Damage

Chromatid aberrations are formed due to damage in one or both the chromatids independently. These aberrations are result of misrepair (joining

of wrong ends) or unrepaired DNA double-strand breaks. Major types of chromatid aberrations are briefly described below and represented in Fig. 7a, b

**Chromatid gaps:** discontinuous staining in small region of one chromatid and no positional changes in chromatids orientation.

**Chromatid breaks:** breaks in on one of the chromatid, and broken end can be observed flipping out of the chromosome.

**Isochromatid gaps and isochromatid breaks:** breaks or gaps in both the chromatid at same position not differentiable from chromosomal gap or break.

**Duplication/deletion** of sequence in one of the chromatid results in bulging of one chromatid at nonhomologous region.

**Chromatid exchange:** just like translocation in chromosomes, chromatids also undergo exchanges resulting into biradial, tetraradial, or complex chromosomal structures.

Chromatid aberrations have significance in clinical diagnosis. The presence of high frequency of chromatid aberrations reflects extensive DNA damage as well as genomic instability. For example, smokers and cancer patients are observed to have higher frequency of chromatid aberrations (Haverić et al. 2016; Pascalis et al. 2014).

### Chromatid,

**Fig. 6** Crossing over; crossing over needs non-sister chromatid pairs, exchange happen through breaking and rejoining

**Chromatid, Fig. 7** Representative images of various types of chromatid aberrations: breaks, gaps, deletion, duplication (a), and chromatid exchanges (b)

## Conclusion

Chromatids are newly formed chromosomes in a cell about to divide into two. They offer a template for restoring damaged part for sister chromatid as well as help in creating variation among gametes by involving in crossing over. Increased levels of damaged chromatids strongly indicate genetic instability and DNA damage which could be associated with cancer and many other clinical conditions.

### Synonyms

[Chromatin](#); [Genetic material](#)

### Definition

Chromosomes are highly compacted form of DNA molecules containing the genetic material

of any organism. Each DNA molecule inside the nucleus is wrapped around histone proteins in a highly ordered manner to form a chromosome.

### Introduction

The degree of compactness of chromosomes is highly flexible and depends on the stage of cell cycle. They are distinctly visible in the mitotic phase (particularly in metaphase), whereas in interphase they are present as indistinct entangled chromosomes fibers called chromatin. Most of the present understanding of packaging of chromatin into chromosome has come from a detailed study of exceptionally giant interphase chromosomes, viz., polytene chromosome in secretory glands of insects and lampbrush chromosome of some vertebrate oocytes.

Chromosomes facilitate the accommodation of huge DNA molecules within a tiny space inside a nucleus or a cell in case of prokaryotes. Total human genome is  $\sim 2(3 \times 10^9)$  bp, which corresponds to a total length of  $\sim 2$  m, and is condensed to approximately 10,000 times to fit in a nucleus with a diameter of few micron.

Prokaryotes have genome compiled in a single circular chromosome, which reside in a cytoplasmic territory called **nucleoid**. In addition to nucleoid, prokaryotes also have extrachromosomal DNA in a form of plasmids having independent replication ability. On the other hand, eukaryotes have larger and complex genome arranged inside a nucleus, and whole genetic material is distributed among several linear chromosomes in single or multiple copies. **Ploidy** describes multiplicity of chromosomes in a cell or organism. Organisms may be **monoploid**, **diploid**, or **polyploid** having only one, two, or more sets of same chromosomes, respectively. Polyploidy is less common among animals but frequently exists in plants. Organisms with asexual reproduction are usually monoploid, while sexually reproducing organisms are diploid. In case of diploid organisms, all somatic cells are diploid but the germ cells are monoploid which is generally referred as haploid, which after fertilization results in the formation of a diploid zygote. Thus, diploid organisms receive half set of

chromosomes from sperm while another half from ovum. The two sets of same chromosome are called **homologous chromosomes**. It should be noted that homologous chromosomes carry the same genes, but they are not identical since they are from two different parents. Eukaryotes also have mitochondrial DNA similar to prokaryotic circular chromosomes which works independently. Each species has a constant characteristic number of chromosomes. Here, it should also be noted that the number of chromosome or size of a genome barely reflects the complexity of an organism. A less evolved species may have larger number of chromosomes (Table 1), for example, *Agrodiaetus shahrami*, a species of butterfly that have 268 chromosomes, the highest number of chromosomes among metazoans (Lukhtanov et al. 2005).

**Essential Features of a Chromosome in Eukaryotic System Includes Origin of Replication, Centromere, and Telomere**

Since the chromosomes contain genetic material of an organism, therefore each chromosome must

be capable of maintaining its integrity, undergoing complete replication and segregated equally between two daughter nuclei during the process of cell division. For these functions, each eukaryotic chromosome is provided with three essential parts: two telomeres, a centromere, and origin of replication (Fig. 1a.). Telomeres are heavily condensed tips of linear chromosomes, which protect the genetic material from degradation. Centromere is a point in the chromosome at which two sister chromatids of a replicated chromosome are held together before cell division attached to the centromere and segregate the duplicated chromosome between two daughter nuclei.

**Organization of DNA into Chromosome Is Achieved in Multiple Levels of Condensations**

Chromosomes have variable degrees of compaction at different stages of cell cycle. Most of the interphase chromosomes are elastic contractile 30 nm fibers known as chromatin. It is difficult to visualize them distinctly under light microscope. However upon chromosome-specific

**Chromosomes, Fig. 1** (a) Basic features of chromosomes. (b) Representation of chromosomal territory inside the nucleus: human chromosome 3 painted in sequence

specific red fluorescent probe shows its localized distribution in interphase nucleus

staining, it is observed that different chromatins do not mess with each other and harbor distinct territory inside the nucleus (Fig. 1b) (Misteli 2008). Thread of DNA-double helix is wrapped around octamer of **histone** proteins named **H2A**, **H2B**, **H3**, and **H4**, two units each. Each set of **histone** proteins with the DNA is known as **nucleosome** making the arrangement popularly known as **beads on a string**. Nucleosomes have ~1.65 round of DNA equivalent to ~145 bp and are connected by non-nucleosomal **linker DNA** of 10–90 bp. Nucleosomes come closer and further condense to 30 nm diameters called chromatin fiber (Fig. 2). Major proportion of chromosomes under normal physiological conditions stays in chromatin form which is a less condensed state that provides accessibility to various proteins and enzymes for gene expression and regulation. However chromosomal condensation is not uniform throughout the length, as telomeric and centromeric regions are highly condensed even in interphase and are termed as permanent **heterochromatin**, whereas the rest of the less condensed part of chromosomes are known as **euchromatin** (Fig. 3). It is notable that

heterochromatin regions are not expressible, gene poor, rich in short tandem repeats, and have higher AT content. Moreover, when expressible genes, by some means, are translocated to a heterochromatin region, they would not express the phenomenon known as **position effect** (Elgin and Reuter 2013). In contrast euchromatins possess expressible single-copy genes and have higher GC content.

### At Higher Condensation Levels, Chromosomes Can Be Distinctly Visualized Under Basic Light Microscopes

During mitosis, interphase chromatins are coiled and further compacted with the help of structural maintenance of chromosome (SMC) complexes comprising **cohesin**, **condensin**, and the **Smc5/6** proteins to make it the most condensed form of chromosomes (Jeppsson et al. 2014). The chromatin fibers form loops around scaffold proteins. At this stage, chromosomes are duplicated and two daughter chromosomes called sister

**Chromosomes, Fig. 2** Illustration of various condensation levels in a chromosome

chromatids glued together with the help of proteins named **cohesins**. Unlike interphase, all the chromosomes in mitotic phase are distinctly visible and countable under light microscope. Hence, mitotic metaphase is the best stage of the cell cycle for the study of overall shape, morphology, and anomalies of chromosomes (Fig. 4).

### Karyotype and Ideogram

A karyotype is an arrangement of chromosomes on the basis of their size and centromere position. As each species has a characteristic number and set of chromosomes, therefore karyotype also is unique for every biological species. Diagrammatic representation of karyotype is termed as karyogram or ideogram (Fig. 5c). Karyotype is prepared on metaphase chromosomes. Each chromosome is identified on the basis of its relative size and centromere position. Moreover, every

chromosome has a characteristic banding pattern upon differential staining based on their GC/AT content. Chromosomes are arranged in a descending order of their size. Karyotype is used to analyze various cytogenetic anomalies for clinical and research purposes.

A karyotype represents the following features of a species/individual:

1. Total number and sets of chromosome
2. Relative size of each chromosome
3. Types of chromosomes based on centromere position
4. Banding pattern
5. Sex chromosomes
6. Cytogenetic anomalies

Karyotype of any normal human will show 46 chromosomes. Out of 46 we have 22 pairs of **autosomes** (chromosomes other than sex chromosome) and 2 sex chromosomes, XX for females

**Euchromatin**

- Lightly stained regions
- Single copy genes
- GC Rich
- Expressible

**Heterochromatin**

- Darkly stained region
- Gene Poor
- Repeat Sequences
- AT Rich
- Inexpressible

and XY for males. The chromosomes are divided into seven groups as described in Table 2.

Aberrations in Chromosomes and Their Clinical Significance

Chromosomal aberrations can be formed as a result of exposure to toxic agents such as alkylating agents, ionizing radiation, etc. These are broadly classified into two categories – **numerical aberrations** referring to changes in counts of the chromosomes which result from **meiotic or mitotic nondisjunction** of chromosomes that is unequal distribution of chromosome between daughter cells during cell division and

second one is **structural aberration** referring to morphological alterations in chromosomes. These are further subcategorized into different classes as depicted in Fig. 6. Structural aberrations include translocation of chromosomal segment to non-homologous chromosomes, joining of two chromosomes (Robertsonian translocation), and dicentric chromosome formation, inversion, and deletion of sequences. Various types of structural aberrations are described through diagrammatic and pictorial illustrations in Figs. 7 and 8.

These aberrations can be acquired from exposure to toxic agents or it can be inherited from parents. Most of the chromosomal aberrations observed are from embryonic stage receiving from one of the gametes and therefore present in

Chromosomes, Table 2 Categorization of human chromosomes based on size and centromere position

| Group           | Chromosome number | Description of chromosomes                              |
|-----------------|-------------------|---------------------------------------------------------|
| A               | 1–3               | Largest, metacentric (1st, 3rd) submetacentric (2nd)    |
| B               | 4–5               | Large, submetacentric                                   |
| C               | 6–12              | Medium, submetacentric                                  |
| D               | 13–15             | Medium submetacentric                                   |
| E               | 16–18             | Small, metacentric(16th) and submetacentric (17th–18th) |
| F               | 19–20             | Small metacentrics                                      |
| G               | 21–22             | Small acrocentrics                                      |
| Sex chromosomes | X                 | Median submetacentric, fits in “C” group                |
|                 | Y                 | Small acrocentric, fits in “G” group                    |

| Two or more Y                                                 | —                    | 44 + XYY male    | Almost normal phenotype                                                                                                                                           |
| Two or more X with Y                                          | Klinefelter syndrome | 44 + XXY male    | Fertility issues, puberty with less prominent male features, enlarged breasts, less body hair, weak muscles, etc.                                                 |

all the cells of affected individual. Although most of the embryos with chromosomal aberrations undergo spontaneous abortions silently during preimplantation stage or within the first trimester, still there are certain chromosomal anomalies which are competent for live births followed by shorter or longer survival age (Table 3). Individuals with such aberrations suffer from multiple health problems and most of them include mental retardations (MacIntyre et al. 2003).

Conclusion

Compact, flexible, and contractile arrangement of DNA into chromosomes allows a cell to properly accommodate the large genetic material, replicate, segregate, and more importantly selectively express the genome. Aberrations leading to alteration in the number of structure of chromosomes may have a range of clinical consequences.

[Grouping](#); [Parsing](#); [Recoding](#); [Sorting](#)

## Definition

Cognitive processes that recode multiple separate stimulus events into groups in memory.

## Introduction

**Chunking** has traditionally referred to cognitive processes that recode multiple separate stimulus events into groups in memory. Chunking has also been referred to as cognitive “recoding,” “grouping,” “sorting,” or “parsing” (e.g., Bower and Springston 1970; Bower and Winenz 1969; Capaldi et al. 1986; Fountain and Annau 1984; Pribram and Tubbs 1967).

Chunking is considered a fundamental process in cognition because it increases memory capacity and efficiency. The idea of chunking was first proposed by Miller (1956) to explain characteristics of human learning, memory, and speech phenomena from a cognitive perspective. Chunking has since been studied widely in a variety of other species by research in the field of comparative cognition (Capaldi et al. 1986; Fountain and Annau 1984; Hulse 1978; Hulse et al. 1992; Suge and Okanoya 2010; Terrace 1987, 1991; Terrace and Chen 1991a, b). Other recent evidence indicates that chunking may also occur as a perceptual process (Gilbert et al. 2014, 2015). Recent developmental research has demonstrated chunking abilities in human infants (Lewkowicz et al. 2018).

## Chunking Manipulations and Cognitive Advantages

Chunking can be manipulated. Research has shown that inserting breaks or pauses (phrasing cues) between chunks facilitates the chunking process (Bruce 1994; Lashley 1951; Spierings et al. 2015; Stempowski et al. 1999). There is also evidence that chunks can be grouped into “superchunks” of information (Capaldi et al. 1990). When elements, chunks, and “superchunks” are organized in hierarchical “structural trees” (Restle 1970) in this manner, both humans

and rats are sensitive to the hierarchical level of individual events (Fountain and Rowan 1995; Restle 1970). Aggregating related information into chunks in this manner decreases working memory load because encoding abstract structure facilitates recalling whole sets of related chunks of information. Thus, not only does chunking facilitate encoding; chunking can greatly reduce the demands on memory capacity.

## Chunking Demonstrations Across Species

Although chunking as a cognitive process was first studied in humans, results from work with animals often parallel those obtained in human studies (Ericsson et al. 1980; Miller 1956; Simon 1974). Chunking has been shown to facilitate learning in multiple modalities and tasks across a variety of species, such as rats, mice, pigeons, songbirds, and primates. The following discussion gives an overview of results observed in sequence, spatial, perceptual, and motor chunking procedures.

### Sequence Chunking

Sequence chunking occurs when animals parse sequences of events or responses into smaller chunks. Using a task where stimuli were presented on a touchscreen, Terrace and colleagues (Terrace 1991; Terrace and Chen 1991a, b) demonstrated that pigeons were capable of chunking information based on colors and shapes. A similar approach using a touchscreen showed that monkeys were also capable of chunking colors and shapes (Swartz et al. 1991). Animals in both studies were presented with series of shapes and colors, and learning the order of stimuli was quicker when similar items were presented together than when stimuli were interleaved. Chunking has also been examined in rats. In a runway task, Capaldi et al. (1990) demonstrated that rats were able to predict serial orders of food quantities and presented evidence that rats could combine chunks into superchunks that contained multiple lists. Rats are capable of chunking items together even when the items are not adjacent in a

sequence (Capaldi and Miller 1988). Other rat research showed that chunking is further facilitated by imposing breaks, therefore creating chunks even when randomly inserted in a complex serial multiple choice task (Fountain et al. 2000; Stempowski et al. 1999). Fountain et al. (2000) found that even unpredictable phrasing cues facilitate better performance on responses following phrasing cues than when no phrasing cues were provided. In addition to using phrasing cues to facilitate chunking, Muller and Fountain (2016) demonstrated that rats are sensitive to the length of chunks using the same serial multiple choice task. Rats were trained on a serial pattern with 3-response chunks and then presented with chunks of differing lengths. When presented with chunks that had more than three responses, rats attempted to make a rule-consistent chunk response after that third element, even in the absence of a phrasing cue. Garlick et al. (2017) observed that pigeons in a touchscreen version of the same task also abstract sequence structure.

### Spatial Chunking

Chunking of spatial locations based on distance from the subject and preference of reward has also been studied in a variety of animals and tasks. Menzel (1973) used a modified traveling salesman task to demonstrate that chimpanzees could chunk locations of food reward in terms of physical location and food preference. Chimps in this study retrieved preferred food items (fruit) before nonpreferred food items which indicated that they chunked preferred food types by location. Using a radial arm maze, Dallal and Meck (1990) and Macuda and Roberts (1995) both reported evidence that rats could also chunk food types by location. De Lillo et al. (1997, 1998) found that monkeys became more efficient at emptying food tray puzzles organized in arrangements that would facilitate chunking strategies relative to tray arrangements that would not facilitate chunking. Evidence for spatial chunking has also been found in bees and fox squirrels. Zhang et al. (1999) found that bees could learn and accurately recall two sets of stimuli to lead to two different locations. Bees were trained on a maze task where the goal was to reach food. When presented with a

landmark on one of two paths, bees accurately chose the correct maze that contained the location, which indicated that they chunked the landmarks with the start boxes of each maze. Delgado and Jacobs (2017) gave wild fox squirrels a variety of nuts and studied how the squirrels cached them. They found that squirrels spatially chunked their caches by nut species.

### **Auditory Chunking**

Auditory chunking, which is chunking of information presented as sounds, has mostly been studied in birds. Williams and Staples (1992) recorded songs of birds and the songs of the birds they had learned from and analyzed song chunks. They found that chunks in the song melodies were consistent with those of the tutor. They concluded that chunking in bird songs is a cognitive learning strategy because syllables were learned in sections with modal lengths of 3. Additionally, the birds delivered the songs with breaks at the chunk boundaries not unlike when humans pause to take a breath between phrases. Similarly, Nicolai et al. (2014) trained bullfinches on human melodies and then analyzed whether the melody was recalled in chunks of notes with pauses between chunks or in a single continuous chain. The finding was that bullfinches recalled songs as chunks of note groups and not chains. Phrasing cues have also been shown to impact auditory chunking (Spierings et al. 2015; Suge and Okanoya 2010). Suge and Okanoya (2010) assessed how inserting phrasing cues into the melody affected song perception and recognition. They trained a bird to respond to a tone (go tone) and then recorded the birds' songs. They then selected a fragment that included a chunk and inserted a sound (phrasing cue) either within the chunk or between chunks. Birds responded slower when the tone was inserted within the chunk relative to when the sound was located between chunks. Using a similar go/no go task, Spierings et al. (2015) assessed how phrasing cues affected chunk recognition in zebra finches by training one group on a melody with pauses and one group on a melody without pauses. Once finches were able to make the discriminations, they were put through reversal learning. The group that had previously been trained with pauses was able to discriminate

between melody chunks in a continuous string of notes while the no-pause group was unable to make distinctions.

### **Motor Chunking**

A final type of chunking found in the literature is motor chunking. Motor chunking occurs when smaller motor movements are chunked into movement sequences. Typically, motor chunking is considered an unconscious or habit-based type of chunking while the other types are considered more conscious strategies. Graybiel (1998) found that sensorimotor responses can be chunked due to activity of the basal ganglia. Ramkumar et al. (2016) used monkeys to assess kinetic movement of center-reach motor movement and found that chunking is a cognitively cost-effective way of moving efficiently.

### **Conclusion**

Whereas Miller (1956) first described chunking through the lens of human cognition, research since then has demonstrated the importance of chunking in both natural and arbitrary tasks in a variety of species. In some of the aforementioned studies, nonhuman animals appeared to chunk information, such as different food types and their locations, without requiring specific experimental manipulations designed to facilitate chunking. Other studies have shown that experimental manipulations such as phrasing cues can encourage animals to use specific chunking strategies. Current research continues to explore the behavioral, cognitive, and neural processes underlying chunking and the limits of this capacity across species.

## Cilia

Hare Krishna

Department of Anatomy, All India Institute of Medical Sciences (AIIMS), Jodhpur, Rajasthan, India

## Synonyms

[Fibril](#); [Filament](#); [Footlet](#); [String](#); [Tendril](#); [Thread](#)

## Definition

Cilia are membrane-bounded, centriole-derived, microtubule-containing, hair-like extensions of the apical plasma membrane.

## Introduction

Cilia are common surface modifications present on nearly all cell types in mammals. The term cilium (Latin word, meaning “eyelash”) was first used by Otto Friedrich Muller in 1786. Cilia were first observed by Antoni van Leeuwenhoek in 1674–1675; he called them animalcules which mean motile thin little feet or little legs (Sengupta 2017).

Initially, the cilia would not be able to gain the importance that it deserved and was relegated to a very minor role in moving out the mucous from respiratory tract. Over the years of research, they found that the cilia were present virtually in every tissue including fallopian tubes, neurons, chondrocytes, limb bud ectoderm and mesenchymal cells, ependymal cells of brain ventricles, kidney tubule epithelial cells, pancreatic duct and islet cells, liver cells, and even many tissue culture cells. In majority of these organs, these cilia were nonmotile so they were considered as nonfunctional (Marshall and Nonaka 2006).

But recently, cilia have important role in migration of cells during development of embryo, sensory signaling pathways, and its association with number of disease syndromes; these organelles become center of attraction for biologists (Bloodgood 2009).

## Classification

Cilia are classified into three categories based on their functional characteristics:

1. Motile cilia
2. Primary cilia
3. Nodal cilia

### Motile cilia

Motile cilia are most extensively studied of all the types and are usually found on the apical domains of epithelial cells of the trachea, ependymal cells of brain ventricles, and on cells lining the fallopian tube and epididymis (Davenport and Yoder 2005). Cilia work in more precise and organized fashion and are responsible for fluid and cell movement in

the body at various sites such as clearance of mucus in respiratory tract, cerebrospinal fluid movement in the ventricles of brain, and the transport of ovum and sperm in their corresponding reproductive tracts. Motile cilia have typical  $9 + 2$  axonemal organization where nine microtubule doublets surround a central pair of microtubules. This central pair has motor protein which is important for the generation of forces inducing motility (Porter and Sale 2000).

#### Function of Motile Cilia

Cilia are motile structure which aids in transport of cells, proteins, foreign particles, and secretions from the epithelial surfaces. They are responsible for the forward movement of the sperm.

#### Primary Cilia (Monocilia)

Most of the vertebrate cells possess a single non-motile cilium per cell called the primary cilium. This microtubule-filled organelle project several microns from the cell surface (Pan and Snell 2007). They are also found in some epithelial cells such as the epithelial cells of the rete testis in the male reproductive tract, epithelial cells in the biliary tract, epithelial cells of kidney tubules, ependymal cells lining the ventricles of the central nervous system, the connecting stalk of photoreceptor cells in the retina, and the vestibular hair cells of the ear. They contain  $9 + 0$  pattern of microtubule instead of  $9 + 2$  arrangement. These are nonmotile because they lack central pair of microtubule and the microtubule-associated motor proteins (Pawlina 2016).

#### Function of Primary Cilia

Primary cilia act as antennae that receive signals from the surroundings. The receptors present on primary cilium mediate light sensations, odorant, and sound perception in multiple organs in the body. The primary cilia also contain various cilia-specific receptors, ion channels, and signaling molecules which act as chemosensors, mechanosensors, and osmosensors. This remote information is converted into signaling cascades that are initiated within the ciliary compartment and then send to the cell cytoplasm.

They also play an important role in the cell cycle and cell differentiation and for normal tissue

morphogenesis in developing tissues (Satir and Christensen 2007).

#### Nodal Cilia

Nodal cilia are found on the bilaminar embryonic disc at the time of gastrulation around the primitive node in the developing embryo. The axonemal internal architecture ( $9+0$  axonemes) of nodal cilium is similar to that of the primary cilium; the only difference is the ability of nodal cilium to perform rotational movement due to presence of motor proteins dyneins or kinesins. (Supp et al. 1997). They generate a leftward flow across the node which is detected by sensory receptors on the left side of the body. After that they initiate signaling mechanisms that differ from those on the right side of the embryo. Any defect in this mechanism causes the left–right asymmetry of internal organs (Nonaka et al. 2002).

#### Function of Nodal Cilia

They are essential in developing left-right asymmetry of internal organs in the developing embryo.

#### Structure of Cilia

Ultrastructurally, Cilium is composed of internal core of microtubules, called axoneme on longitudinal section. But on cross-sectional view, it contains either nine pairs of microtubules or doublets of nine microtubules surrounding two central microtubules. The microtubules composing each doublet are composed of two types of microtubule – A microtubule and B microtubule. The A microtubule is composed of 13 tubulin protofilaments whereas the B microtubule is composed of 10 tubulin protofilaments (Fig. 1).

Each microtubule A exhibits a pair of “arms” that contain a motor protein “dynein.” The protein “nexin” permanently links the microtubule A with the microtubule B of adjacent doublets. Each of the nine doublets give rise to radial spokes, toward the two central microtubules. The  $9 + 2$  microtubule arrangement is continuous from the tip of the cilium to its base, whereas the outer paired microtubules join the basal body. Basal body with the

**Cilia, Fig. 1** Structure of motile cilia. (Source: <https://commons.wikimedia.org/w/index.php?curid=3145956>)

help of basal body-associated structures anchors cilia in the apical cell cytoplasm.

## Ciliary Diseases

1. Primary ciliary dyskinesia or immotile cilia syndrome: Immotile cilia affect various system of the body.
  - (a) Respiratory system: chronic respiratory distress with persistent cough, bronchitis, asthma, and sinusitis
  - (b) Ear: Otitis media
  - (c) CNS: Hydrocephalus internus or transient dilatation of inner brain ventricles
  - (d) Reproductive system: sterility
2. Polycystic kidney disease: In this disease, there is mutation in genes which are required for polycystin1, polycystin 2, and fibrocystin protein synthesis. Polycystin-1, located within the cilium (9+0 arrangement), acts as a mechano or chemo sensor and help in transmission of the signal from the extracellular fluid compartment to the interacting  $\text{Ca}^{2+}$ -channel polycystin-2. Polycystin-2 then mediates sufficient  $\text{Ca}^{2+}$  influx to activate intracellular ryanodine receptors resulting in intracellular  $\text{Ca}^{2+}$  release. Mutations in Polycystin-1 or Polycystin-2 might disable cilia-mediated mechanosensation, which is normally required

for tissue morphogenesis. Thus, these mutations in Polycystin-1 or Polycystin-2 can cause polycystic kidney disease (Sun et al. 2004).

3. Kartagener's syndrome: There is absence of dynein arms which result in failure of mucociliary transport system.
4. Situs inversus: due to defect in nodal cilia.
5. Other emerging ciliary diseases due to ciliary involvement:
  - (A) Retinitis pigmentosa
  - (B) Bardet-Biedl syndrome (Beales 2005)

## Conclusion

Cilia are emerging as omnipresent organelles which act as antennae sensing the external environment. Their defects in structure are responsible for an increasing number of disease syndromes. Almost all mammalian cells have a cilium; the functions of cilia in many organs are now known but in many other organs have not been known at all. We are only just beginning to understand, so a lot of researches are also needed to know other facts about cilia.

## Circadian Rhythm

### ► Biological Clocks

## Circadian Rhythms

Christian Petersen and Ralph Mistlberger  
Simon Fraser University, Burnaby, BC, Canada

### Introduction

The rotation of the earth about its axis once every 24 h creates daily rhythms in light, temperature, humidity, and other factors that present both

challenges and opportunities for life on earth. It is therefore no surprise that daily rhythms in behavior and physiology are found in almost all living organisms, from single cell bacteria to humans. Most daily rhythms reflect the output of internal biological clocks that cycle with a periodicity close to 24 h. Rhythms generated in this way are classified as “circadian” (from the Latin *circa*, about and *dies*, day). Circadian clocks are believed to have evolved early in the history of life, possibly to restrict cellular processes, such as DNA replication, to the night, to avoid the damaging effects of ionizing radiation from sunlight. The adaptive value of synchronizing cellular and behavioral activities with the outside world led to the incorporation of circadian clocks into the biochemistry and physiology of nearly every organism on the planet. By internalizing the mechanism for rhythmicity, organisms gain the ability to prepare in advance for predictable daily environmental changes, rather than merely react to them.

The biologists and physicians who initiated formal analysis of circadian rhythms in the 1950s adopted the terminology employed by physicists and mathematicians to describe oscillatory processes (see Fig. 1). A rhythm is defined as any process that repeats itself at regular intervals. A device that produces a rhythm is an “oscillator.” A rhythm can be described by two parameters. One parameter is the rhythm “period” (often denoted by the Greek letter  $\tau$ ), which is the duration of a complete cycle. The other is rhythm “amplitude,” which refers to the range of values that a rhythm exhibits across the cycle. Amplitude may be expressed as the difference between the maximum value and the mean, or the maximum and minimum. “Phase” (often denoted by the Greek letter  $\phi$ ) refers to any discrete point or range of points within a cycle. If a circadian rhythm is modeled as a sine wave, then the peak value is the acrophase, and the amount of time between successive acrophases is the period.

### Entrainment

A defining feature of circadian rhythms is that they are endogenously generated. The most compelling

**Circadian Rhythms, Fig. 1** Sine wave representing the output of a rhythmic process, labeled according to conventional terminology in the field of circadian biology. Rhythm period is the duration of the complete cycle (often denoted by the Greek letter  $\tau$ ). Amplitude is the difference between the maximum and minimum values or

the maximum and the mean value. Phase is any point or range of points within a cycle (often denoted by the Greek letter  $\phi$ ). A Zeitgeber is any periodic stimulus that can entrain the rhythm. Zeitgeber time (ZT) is plotted in hours, where ZT0 corresponds to lights-on, by convention

evidence for this is that they persist, or “free run,” in “constant conditions” (environments lacking external time cues). In constant conditions (e.g., a cave or a laboratory vivarium in constant dark), the periodicity of the persisting rhythm is generally close to, but rarely exactly 24 h, hence the designation “circadian.” Consequently, circadian rhythms gradually drift out of normal alignment (“out of phase”) with the outside world (Fig. 2A, B). This property rules out the possibility that circadian rhythms are driven by uncontrolled external stimuli.

Given that circadian rhythms free-run with periodicities close to, but not exactly, 24 h, a mechanism must have evolved by which they can be synchronized to the external environment. Indeed, without a way of establishing a stable phase relationship to the solar day, circadian rhythms would likely be maladaptive. Synchronization of circadian rhythms to 24-h light-dark (LD) cycles is achieved by “entrainment,” defined as phase and period control of an oscillator by a periodic stimulus. It is through this active process that the mechanism driving circadian rhythms is transformed from an oscillator to a bona fide clock that matches and is therefore predictive of environmental time.

In the process of entrainment, the circadian clock is reset, or “phase shifted,” by external time cues (“zeitgebers”; from the German, “time-givers”). The magnitude and direction of phase shifts depends on both the timing and physical magnitude (e.g., intensity or duration) of the zeitgeber. The mechanism by which circadian rhythms are entrained to the 24-h LD cycle has been investigated by exposing animals to brief pulses of light during prolonged recordings in constant darkness. Light exposure late in the biological night (that portion of the circadian cycle during which the animal behaves as though it were night) and early in the biological day pushes the clock ahead to a later phase (a “phase advance”; Fig. 2A), while light late in the “biological day” and early in the “biological night” resets the clock to an earlier phase (a “phase delay”; Fig. 2B). Therefore, the response of circadian clocks to light exposure depends on the circadian phase at which the light exposure occurs. This can be represented by a “phase-response curve,” which plots the size and direction of phase shifts induced by light exposure at different points within the circadian cycle (Fig. 2C). Under a natural photoperiod, phase shifts induced by light exposure at dawn or dusk

**Circadian Rhythms, Fig. 2** How light entrains circadian rhythms. Panels A and B represent the circadian wheel running rhythms of Syrian hamsters maintained in constant dark. Each line represents 24 h of recording, and consecutive days are aligned vertically. The black bars indicate wheel running, and the blank sections indicate rest. These graphs show that wheel running is concentrated into one major bout each day, and that this bout begins at few minutes earlier each day (the periodicity is “circadian”). The single star on each chart represents a 30 min light exposure. In Panel A, the light pulse occurred at the end of the daily active phase and caused the onset of activity to occur earlier than usual the next day, defining a phase advance shift. In Panel B, the light pulse occurred earlier in the active phase, and activity onset occurred later than usual the next day, defining a phase delay shift. Panel

C illustrates the results of many such light exposures, summarized in a phase response curve in which the size and direction of the phase shift is plotted according to the circadian time of the light exposure. Circadian hours 0–12 represent the biological day, and hours 12–24 the biological night. Light early in the biological night induces phase delays, while light later in the biological night induces phase advances. Panels D and E illustrate the effects of phase shifting the LD cycle by 8 h either forward (D, an advance) or backward (E, a delay). The circadian rhythm gradually advances or delays taking about 8–10 days to reentrain. Panel F shows that circadian rhythms can be entrained by two daily light pulses (the thin opaque vertical bars), simulating dawn and dusk. With one daily light pulse, the rhythm gradually begins to delay a small amount

precisely compensate for the difference between the free-running period of the circadian rhythm and the period of the LD cycle. A rhythm with a period less than 24 h will naturally advance each day relative to the solar day, but is prevented from doing so because exposure to evening light causes a daily delay shift. A rhythm with a period greater than 24 h will naturally delay relative to the solar day, but this is prevented by morning light which induces a daily advance shift. The bidirectionality of the phase shift response ensures that the

rhythm is locked into a stable phase relationship with the solar day, regardless of whether the underlying circadian clocks naturally run fast or slow relative to 24 h. This mechanism can produce stable entrainment even if there is only one or two daily light pulses, simulating dawn and/or dusk (Fig. 2F).

Phase shifts in response to light typically exhibit a maximum size, on the order of a few hours, depending on light intensity and duration. As a result, entrainment can occur only if the period of

the LD cycle is within an hour or two of 24 h. LD cycles longer or shorter than this exceed the phase shifting capacity of circadian clocks, resulting in a circadian “limits to” or “range of” entrainment. Circadian rhythms under non-24 h LD cycles will either free run through the LD cycle or show “relative coordination,” as light exposure produces delays or advances that are not sufficient to offset the difference between the period of the LD cycle and the period of the circadian cycle. These limits in the magnitude of phase shifts explains the gradual resynchronization of circadian rhythms following a rapid shift in the LD cycle, such as is encountered following transmeridian jet travel (Fig. 2D, E). The temporary mismatch between environmental time and circadian (biological) time results in symptoms of jetlag (most commonly experienced as disruptions of sleep, alertness, appetite, and digestion).

### The Molecular Basis of the Circadian Clock

Given that single cell organisms exhibit true circadian rhythms, the clock mechanism in these species

must be intracellular, but the same is true of all multicellular organisms. Research on fruit flies first revealed that circadian rhythms are based on cycles of gene transcription involving so-called “circadian clock genes” encoding proteins that regulate their own expression by negative feedback (Fig. 3). Similar autoregulatory transcriptional oscillators drive circadian rhythms in other life forms. Archaea, bacteria, plants, and fungi utilize entirely distinct sets of clock genes, while fruit flies and vertebrates share some clock gene homologues. Regardless of the specific genes, all of these transcriptional oscillators are based on the principle of negative feedback, representing a remarkable example of convergent evolution.

In mammals, the transcriptional oscillator works as follows. Transcription of two clock genes, *Clock* and *Bmal1*, yields messenger RNAs that are translated into corresponding clock proteins, CLOCK and BMAL1, that partner to form heterodimers. The CLOCK:BMAL1 protein complex binds to the promoter regions and activates transcription of three *Period* genes (*Per1*, *Per2*, *Per3*) and two *Cryptochrome* genes (*Cry1* and *Cry2*). The PER and CRY proteins

**Circadian Rhythms, Fig. 3** Schematic representation of the cellular clock gene loop. Briefly, the clock genes *Clock* and *Bmal1* encode the proteins CLOCK and BMAL1, which dimerize and activate transcription of the genes *Per* and *Cry*. PER and CRY proteins dimerize, translocate from the cytoplasm to the nucleus, and suppress activation

of the *Per* and *Cry* genes by blocking CLOCK and BMAL1. As PER and CRY proteins are degraded, suppression is eventually relieved, and transcription of *Per* and *Cry* is renewed, initiating the next cycle. Accessory loops and posttranslational modifications of clock proteins stabilize and set the period of the cycle to approximately 24 h

encoded by these genes form partners, translocate from the cytoplasm to the nucleus, and block CLOCK:BMAL1 binding to the *Per* and *Cry* gene promoters. This turns off transcription of the *Per* and *Cry* genes. PER and CRY proteins are gradually degraded and removed, freeing CLOCK and BMAL1 to activate the *Per* and *Cry* genes again, initiating the next cycle. The rate of transcription and the abundance of PER and CRY proteins are further regulated by accessory loops and several posttranslational modifications that help set the period of the oscillation to the circadian range, and enhance precision and amplitude (Ko and Takahashi 2006). Some of these core clock genes regulate expression of other genes (“clock-controlled genes”), which in turn modulate expression of more genes such that a significant portion of the genome comes under clock control, thereby conferring circadian rhythmicity to a broad range of cellular functions. Despite the number of cycling genes, it is possible to break the circadian clock and eliminate circadian rhythms by removing just one clock gene (*Bmal1*). Mutations of other clock genes can alter the period of the circadian cycle (in some cases explaining why some people are extreme early birds or night owls), or in some combinations, either weaken or eliminate circadian rhythmicity. These represent remarkable examples of how striking behavioral phenotypes can be explained by changes in expression of just one or two genes.

The discovery of a mechanism for circadian clocks, based on self-sustaining oscillations of gene transcription, that generalizes across phylogeny is one of the great accomplishments in molecular biology. However, the story is not yet complete, as circadian rhythms in at least some cell functions have recently been discovered in cells that lack DNA (e.g., human red blood cells). The mechanism underpinning these rhythms remains an open question (Hoyle and O’Neill 2015).

## The Structure of Circadian Systems

If the circadian clock is intracellular, where in multicellular organisms are circadian clock cells

located? Another seminal discovery in circadian biology was the recognition that circadian clock cells are found in most, if not all, tissues and organs. This raises interesting questions concerning how the circadian oscillations of clock cells are synchronized within and between tissues. Without a mechanism for intercellular synchrony, circadian oscillations at the cellular level would not translate into circadian oscillations at the tissue and organ level, and organ functions would be arrhythmic, rather than circadian. This problem was solved in part by the evolution of hierarchically structured circadian systems, in which one or more master circadian clocks (pacemakers) preside over many local circadian oscillators, analogous to the role of a conductor in an orchestra.

The first circadian clock to be identified in mammals was the suprachiasmatic nucleus (SCN), a relatively tiny collection of neurons and glial cells (only ~20,000 neurons among the billions that comprise the brain) residing at the base of the brain, on top of the optic chiasm (Fig. 4a). A majority of neurons in the SCN express circadian oscillations. While cells in many other brain regions and most body tissues are capable of oscillating, the SCN is unique in its ability to maintain synchrony within its population of clock cells in the absence of external synchronizing inputs. SCN neurons are coupled primarily via synaptic connections that enable it to produce a unified coherent output that is then communicated to the rest of the brain and body. Clock cells in most other tissues lack sufficient intercellular coupling to retain a population rhythm without direct or indirect synchronizing signals from the SCN pacemaker.

The status of the SCN as a “master pacemaker” is supported by several lines of evidence. First, destruction of the SCN eliminates circadian rhythmicity of behavior and physiology (Fig. 4b). Second, electrical or chemical stimulation of SCN neurons shifts the phase of behavioral and physiological rhythms. Third, SCN neurons, both in vivo (in the brain) and in vitro (in cell culture outside of the brain), show circadian oscillations in neural firing rate, glucose uptake, neuropeptide secretion, and gene expression. Finally, following

**Circadian Rhythms, Fig. 4** (a) Photomicrograph of a mouse brain stained for the neuropeptide VIP, which is abundantly expressed within the SCN. The SCN is located bilaterally above the optic chiasm and below the 3rd

ventricle. (b) Double plotted activity record (actogram) depicting wheel running activity in a mouse with a complete lesion of the SCN. All circadian rhythmicity in wheel running activity has been abolished

complete ablation of the SCN, circadian rhythms of behavior can be restored by transplants of fetal SCN tissue. The periodicity of the restored rhythm is determined by the genotype of the donor tissue and not that of the host, proving that the donor SCN is indeed the source of the rescued rhythmicity.

The efferent pathways responsible for communicating circadian rhythmicity from the SCN to the rest of the brain and body appear to involve both neural and humoral mechanisms. The SCN sends axonal projections to a relatively small number of other brain areas, mostly located within the hypothalamus. These brain regions control sleep and wake, feeding and drinking, body temperature, and endocrine secretions that distribute circadian timing information to additional brain regions. Circadian oscillators located outside of the brain are controlled by autonomic efferent nerves, pituitary endocrine secretions, the daily body temperature rhythm, and various stimuli associated with the daily feeding and drinking rhythms. These signals determine the timing of local circadian oscillators in a tissue specific manner, to ensure appropriate coordination of biochemical and physiological processes within and between different organs and organ systems. As

discussed below, under certain conditions, peripheral tissues are capable of either altering their phase relationship to the SCN or ignoring the SCN altogether, indicating flexibility inherent in the system.

### Clock Inputs: Light and Food

In the mammalian brain, SCN neurons are the first to receive information from the retina, via a retinohypothalamic tract (RHT) dedicated to entraining the SCN circadian clock to daily LD cycles. The RHT is composed of axonal projections arising from a specialized subset (~5%) of retinal ganglion cells that contain the photopigment melanopsin and are able to respond directly to light. These intrinsically photoreceptive retinal ganglion cells (ipRGCs) receive input from rod and cone photoreceptors, but are fully competent to mediate LD entrainment without rods and cones. Rods and cones are required for conscious vision (i.e., to see objects and movement); therefore, it is possible to be completely blind, and yet still entrain to LD cycles, as long as the ipRGCs are intact (Guler et al. 2008). Absorption of light by melanopsin activates ipRGCs,

which then release the neurotransmitter glutamate from their axon terminals in the SCN. Glutamate activates SCN neurons by opening ion channels for sodium and calcium. This initiates a series of biochemical reactions in SCN neurons that increase expression of the *Per* genes and enhance production of PER protein levels. If exposure to light occurs when *per* gene expression is normally falling (i.e., early in the biological night), increased *Per* transcription raises PER protein levels to where they were earlier in the cycle, thus delaying progression of the clock gene cycle and resulting in a phase delay. Conversely, light exposure late in the biological night, when *Per* gene expression is rising, accelerates protein production, advancing progression of the cycle and resulting in a phase advance. Thus, the same action (increased *Per* expression) can have opposite phase shifting effects depending on the phase at which it occurs (Dibner et al. 2010).

Light is not the only stimulus that can act as a zeitgeber for circadian rhythms. “Nonphotic” stimuli that can entrain circadian clocks include temperature, food intake, social cues, and behavioral arousal (Mrosovsky 1996; Mistlberger and Skene 2004). The importance of these varies by species and body tissue. In some mammalian species, the SCN pacemaker, and therefore the entire circadian system, can be shifted or entrained by stimuli that evoke behavioral arousal. This may be the means by which circadian rhythms in some of these species are entrained by social interactions. Arousing stimuli act on the SCN via inputs from several different brain structures, including the pontine Raphe nuclei, thalamic intergeniculate leaflet, and basal forebrain. Whereas photic zeitgebers are most effective at times of day when light is normally absent (i.e., the biological night), in general, nonphotic cues exert their strongest effects at times when the animal would normally be asleep (i.e., the biological day for nocturnal rodents) (Webb et al. 2014).

Daily feeding schedules can entrain the entire circadian system in some species, while entraining many but not all circadian clocks in other species. In Syrian hamsters and some mouse strains, a daily feeding schedule, imposed in the absence of a LD cycle, can entrain the

entire circadian system such that the daily active phase is synchronized with and anticipates mealtime. Food entrainment in these cases includes the SCN pacemaker and likely all local oscillators throughout the body. In many other species, including rats and some other mouse strains, temporally restricted food intake often does not entrain the SCN pacemaker, but does control the phase of circadian clocks in most other brain regions and body tissues. As a result, metabolic and physiological rhythms shift to align to the daily mealtime, so that the animals are prepared to ingest, digest, and distribute nutrients critical for survival. Importantly, one or more of these food-entrainable oscillators (FEOs) generates a behavioral rest-activity cycle, resulting in a daily rhythm of food anticipatory activity (FAA). This enables animals to adjust their daily foraging rhythms to exploit temporal regularities in food availability and focus food-seeking activity at the most productive times of day. In these species, the SCN pacemaker remains entrained to the LD cycle, while foraging behavior is controlled by a food-entrainable clock (Mistlberger 1994).

The evidence that FAA is controlled by a true circadian clock separate from the SCN is as follows. First, once FAA has developed, it persists for multiple days when feedings are withheld. Second, when mealtime is abruptly shifted, FAA does not immediately reset, but rather, shifts gradually. Third, FAA exhibits circadian limits to entrainment and does not emerge if meals are scheduled at noncircadian intervals (outside of the ~22–30 h range). Finally, while SCN ablation eliminates circadian rhythms when food is freely available, if food is restricted to a fixed daily mealtime, circadian rhythms of FAA emerge, and circadian organization of metabolism and physiology are restored. Entrainment of circadian clocks by food is also preserved in mice with clock gene mutations that eliminate or disrupt circadian rhythms entrained to LD cycles. When light-driven and food-driven rhythms diverge, most tissues, both centrally and peripherally, entrain to the feeding rhythm, with the SCN being the primary exception (Mistlberger 2011; Schibler et al. 2003).

The location of FEOs that control FAA remains to be determined. The available evidence suggests that FAA is controlled by a broadly distributed system of FEOs in the brain and possibly also the body. Some species are able to anticipate at least two daily meals, and possibly more, without the SCN. Whether this involves one FEO being used like a wristwatch to recognize and remember multiple mealtimes, or multiple FEOs entraining independently to different mealtimes, is unknown.

## Circadian Flexibility

Just as organisms are specialized for particular spatial niches, so too are they specialized for particular temporal niches. Raptors have evolved remarkable visual acuity enabling them to hunt small terrestrial prey while flying high above the ground, but this visual adaptation works only in daylight. The temporal niche of a species is typically defined as the time of day when they are most active (engage with the environment). Temporal niches include nocturnal (night-active), diurnal (day-active), and crepuscular (dawn and dusk active). Some species conform to none of these patterns and are classified as cathemeral (active during both day and night).

Despite these well-known categories, many animals are not rigidly nocturnal or diurnal. Temporal niche preference can instead be thought of as a continuum from the nearly entirely diurnal grass rat (with ~90% of its daily activity occurring during the light phase) to the nearly entirely nocturnal Syrian hamster (with well over 90% of its activity occurring during the dark phase) (Refinetti 2006).

Further complicating classification, marked differences in temporal niche preference can exist between individuals within a species. An extreme example of this is provided by the degus (*Octodon degus*). Under standard laboratory conditions, most degus exhibit a clear diurnal activity profile, while in a subset of individuals, activity is concentrated at night. More common are less dramatic individual differences in circadian timing that are likely the result of differences in free-

running period or responsiveness to zeitgebers, giving rise to the distinction between “morning lark” and “night owl” types within species.

Individual animals are also capable of changing temporal niche. These changes can occur as a result of natural changes across the lifespan, such as a hormonal-based pubertal shift that occurs in humans, degus, and possibly other species (Hagenauer and Lee 2012). As discussed above, many species can entrain to daily feeding schedules, and forage for food at times of day when they normally would sleep, if that is when food is most likely to be found. Temporal niche switching can also be triggered by metabolic challenge. For example, nocturnal mice that are forced to work for food show a gradual shift to diurnality that coincides with a gradual shift toward a negative energy balance. The shift to daytime activity allows the animals to sleep and lower their body temperatures at night, when it is normally cooler (at least, throughout evolutionary history in natural habitats). This reduces energy expenditure associated with thermoregulation. Niche switching can also be induced by competition within and between species (Hut et al. 2012).

The biological basis for phase differences in circadian timing is still unclear. Although nocturnal and diurnal animals differ dramatically in the phase relationship between the sleep-wake cycle and the LD cycle, the phase relationship between the SCN and the LD cycle is identical in both types of animals. Firing rates and *Per* gene expression in the SCN peak at approximately the same phase in both diurnal and nocturnal species, suggesting that their differences in temporal niche preference are a result of activity downstream from the master pacemaker (Smale et al. 2003). Temporal niche switching also appears to be due to factors downstream from the SCN. Mice displaying a diurnal activity profile when forced to work for food immediately revert to a nocturnal profile when food is provided freely, indicating that the phase of the SCN remained unaltered.

This flexibility in the phase relationships between the LD cycle and activity highlights an adaptive feature of the circadian timekeeping

system. It is clear that this system did not evolve to rigidly synchronize organisms to the day-night cycle, but rather to enable behavior and physiology to take full advantage of other predictable daily events or adapt to metabolic challenges. While the LD cycle is a ubiquitous environmental time cue for most terrestrial life forms, the circadian system is capable of altering its phase relationship to the solar day (as in the case of temporal niche switching) or ignoring LD cycles altogether when other stimuli (such as food availability) have more immediate consequences for survival.

## Circadian Rhythms and Cognition

Circadian clock genes oscillate in numerous brain regions, and it is therefore not surprising that cognitive processes exhibit circadian variation (for a thorough review see Smarr et al. 2014). Circadian variation is at least partly secondary to circadian regulation of behavioral state, which determines how alert animals are at different times of day. Circadian clock genes may also directly modulate cellular functions that mediate neuronal processes critical for attention, learning, and memory. Whether direct or indirect, the net result of circadian regulation are daily rhythms in attention and performance on various forms of associative and nonassociative learning and memory tasks, with peak performance typically in the organisms active phase, but sometimes in the rest phase.

If circadian clocks in the brain modulate cognitive processes, then disruption of circadian rhythms may impair cognitive performance. Disruption can be induced by exposing animals to constant lighting or LD cycle shifts, by SCN ablation or by clock gene mutations. LD shifts scheduled just before or during training impairs memory for places associated with rewards, punishments, or escape locations. Performance on these tasks is dependent on the hippocampus, a brain region critical for various forms of learning and memory. Circadian rhythms in the hippocampus are disrupted by SCN lesions, which may explain the deficits in memory for objects and rewarding places in hamsters with

SCN damage. The hippocampus shows circadian oscillations in various cellular functions, including synaptic plasticity and circadian clock gene expression. Disrupting circadian oscillations in the hippocampus itself can interfere with long-term memory formation (Eckel-Mahan et al. 2008).

Another way in which circadian clocks contribute to animal cognition is by providing a continuous readout of time of day that can be incorporated into event memories. Some species, among bees, fish, birds, and rodents, can remember the time of day that food is available at specific places in their foraging range. These species can discriminate time of day, even if no external circadian time cues are available. They must therefore be attaching an internal representation of circadian phase to the feeding event memory. This circadian time-place learning is a powerful adaptation for those animals that must forage widely for food that may vary both in time and place (Mulder et al. 2013).

The neurobiological basis of circadian time-place learning remains to be determined. A candidate circadian clock for time-place learning is the SCN. However, if the SCN does participate in time-place learning, it is apparently not required, at least when food acquisition is the event, because rats with complete SCN lesions exhibit normal time-place learning in the lab (Mistlberger et al. 1996). This suggests that FEOs that generate food anticipatory rhythms may also provide circadian time cues that associate with place information in event memories.

Circadian time cues are also used by animals, such as bees, butterflies, and birds, that can use the sun and stars as a compass for navigating and long distance migration. The sun moves across the sky at 15°/h. It can be used as a directional cue, as long as the heading relative to the sun is adjusted by the same amount each hour. This can only be done if there is an internal chronometer that can measure the passage of time, with at least hourly resolution. Experiments dating back to the mid-twentieth century have established that a circadian clock in birds, insects, and other animals can be used in this way, to permit time-compensated, sun-compass orientation (Schmidt-Koenig 1990).

## Conclusion

Circadian rhythms evolved early in the history of life on this planet. These rhythms enable optimal coordination with the environment by providing the organism with the ability to prepare for regularly recurring events, such as the daily light-dark cycle or daily variations in food availability. Circadian clocks modulate almost all aspects of physiology, behavior, and cognition and can also be utilized directly in memory formation, providing organisms with the ability to link a representation of time of day to event memories. The remarkable flexibility of the circadian system provides organisms with the ability to optimize the timing of their behavior to best take advantage of their environment.

[Blood](#); [Cardiovascular system](#); [Circulation](#); [Heart](#)

### Introduction

The circulatory system is a complex system of organs and vessels that has the main function of transporting substances throughout the body. It transports blood, nutrients, hormones, and oxygen to different body organs, which are needed by tissues for survival. Along with transporting substances to tissues, it also functions to carry carbon dioxide and other wastes away from the cells (Riedesel and Engen 2015).

Another function of the circulatory system is to assist with thermoregulation (regulating body temperature). While blood circulates throughout the body, it assists with temperature stabilization by absorbing the heat released by cells during daily activity. When an increase in body temperature is noted, blood vessels in the skin begin to dilate and blood flow to the skin increases, which allows heat to be released away from the body. Conversely, when a body temperature drop occurs, blood vessels in the skin constrict and blood flow to the skin decreases, which enables heat retention by the body.

In animals, circulatory systems vary from simple to complex. All vertebrates and some invertebrates utilize a closed circulatory system where blood is strictly transported in vessels. Other invertebrates utilize an open circulatory system, where blood is found both inside vessels and in body cavities. This chapter primarily covers the vertebrate, and specifically the mammalian, circulatory system, which is a closed system.

## Circulatory Structures and Functions

The main components of a closed circulatory system include blood, the heart, and the vessels. The vessels are divided into arterial vessels, capillaries, and venous vessels. Some sources also include the lymphatic system as a component of the circulatory system.

**Blood** is a solution primarily consisting of plasma, red blood cells, white blood cells, and platelets (World Book inc 2015). Plasma is the main component of blood. It is a liquid medium that contains multiple substances including water, proteins, and minerals. Red blood cells, also known as erythrocytes, function to transport oxygen and carbon dioxide throughout the body. White blood cells, also known as leukocytes, function in immune defenses, protecting the body from disease by attacking and eliminating cells they perceive as foreign. Platelets, also known as thrombocytes, are essential cells that function in the clotting cascade to assist with the prevention of blood loss following injury to vessels (World Book inc 2015).

Blood is essential for the transportation of toxic substances such as carbon dioxide, salts, and ammonia, from cells to the liver. In the liver, the hazardous materials are converted into substances that can be eliminated from the body through the kidneys (World Book inc 2015).

Once the small intestines digest food that is ingested by the body, the nutrients from these digested foods pass into the blood via capillaries. Blood then transports these substances to the liver. The liver will then either store or release the nutrients to cells for daily activities such as energy production.

Blood volume varies between species, depending on body size and activity level. As activity level increases, blood volume has been noted to increase. Some animals, such as marine mammals, have larger blood volumes due to their need for increased blood oxygen stores. Some of the animals with the largest blood volumes are the species that are the most active and tend to have longer dive times, such as elephant seals, Weddell seals, and sperm whales. Their bodies may contain a blood volume of 200–260 ml/kg of body

weight, compared to approximately 70 ml/kg of body weight in adult humans (Ponganis 2009).

**The Heart** is a major muscular organ that functions to pump blood throughout the body. The anatomy of the heart differs between species.

In mammals and birds, the heart is divided into four chambers, with two separate pumps for systemic and pulmonary circulations (Stephenson et al. 2017). The chambers include right and left atriums divided by an interatrial septum and right and left ventricles divided by an interventricular septum. The flow of blood from each atrium to their respective ventricle is regulated by a series of valves. The anatomical variation of two separate pumps allows for the separation of unoxygenated blood, which is being delivered to the lungs by the right side of the heart, from the oxygenated blood, which is being pumped to the systemic circulation by the left side of the heart (Burggren et al. 2014). This separation enables the right side of the heart to function as a low pressure pump to the lungs, while the left side of the heart functions as a high pressure pump to systemic circulation (Burggren et al. 2014). As blood flows from areas of high pressure to areas of low pressure, the interatrial septum and interventricular septum play essential roles in ensuring that oxygenated blood makes it to the systemic organs that require oxygen to function.

**Arterial vessels** function to pump blood from the heart to the different body systems and body organs. These vessels are primarily controlled by neuronal impulses and local metabolic control. The arterial vessels consist of a high-resistance system and include the aorta, arteries, and arterioles.

The aorta is the major arterial vessel that extends from the heart to the abdominal cavity. It functions to carry oxygenated blood into the abdominal cavity for disbursement to body tissues.

Arteries function to carry blood away from the heart. Most arteries carry oxygenated blood from the left side of the heart to the remainder of the body, with the exception of the pulmonary artery. The pulmonary artery functions to take unoxygenated blood from the heart to the lungs.

Arterioles are smaller vessels which provide the main source of blood flow resistance in the

cardiovascular system (Martinez-Lemus and Laughlin 2015). They provide this resistance by vasodilating (enlarging) in areas that are in need of blood flow and vasoconstricting (shrinking) in areas that are not in need of a larger flow of blood. These are the structures that are the primary determinant of systemic blood pressure, and the pressure the heart is required to produce to ensure blood is pumped to the body systems. Systemic blood pressure is controlled by the heart rate (how many times the heart beats per minute) and the stroke volume (how much blood is pumped by each heartbeat). The size of the arterioles determines how much pressure the heart needs to overcome in order to pump blood to the body systems. How easily the heart is able to overcome this pressure gradient will determine how much stroke volume is produced.

Normally, arterioles remain in a partially constricted state (basal tone). Different tissues display different levels of basal tone depending on the tissue's resistance need. This basal tone helps prevent a sudden and dangerous decrease in systemic blood pressure if a tissue suddenly needs a large amount of blood flow, which causes the vessels to reach their maximal dilated potential (Riedesel and Engen 2015).

**Capillaries** are small vessels that function to provide gas and nutrient exchange between blood and body tissues and between arteries and veins. Being constructed with a wall thickness of only one endothelial cell enables capillaries to filter the fluid that is being transferred between the vessels and the body. Differentiated based on the number and size of pores in their endothelial walls, capillaries are found in three types: continuous, sinusoidal (discontinuous), and fenestrated. Continuous capillaries, with whole endothelial walls and basement membranes, allow water-soluble ions and molecules to cross between cells through pores or intercellular clefts. Discontinuous capillaries are required for larger whole cells, macromolecules, and particles to cross between cells as they consist of gaps between the endothelial cells and an incomplete or absent basement membrane. Fenestrated capillaries contain small pores covered by a thin diaphragm which allow water and solutes to permeate

through the capillary wall (Martinez-Lemus and Laughlin 2015).

**Venous vessels** act to collect blood and transport it back to the heart. These vessels, which consist of both elastic tissue and smooth muscle cells, are primarily controlled by neuronal impulses (Yin 2010). This system is a low-pressure system. The main types of venous vessels include veins, venules, the cranial vena cava, and the caudal vena cava.

The primary functions of veins are storage of unoxygenated blood and carrying the unoxygenated blood back to the heart from the systemic circulation. The exception to this is the pulmonary veins, which carry oxygenated blood back to the left atrium of the heart from the lungs. Veins are responsible for storing 60–80% of the circulating blood volume (Yin 2010).

Venules are small vessels that carry unoxygenated blood from the capillaries and converge to form veins.

The cranial vena cava is a large vein that extends to the cranial aspect of the body, from the heart towards the head. The caudal vena cava is a large vein that extends to the lower aspect of the body.

## The Lymphatic System

The lymphatic system is essential for maintaining appropriate plasma volume. This system is unique to vertebrates and includes lymphatic vessels, lymph nodes, and lymphoid organs. Lymphatic vessels can be found throughout the body in almost all vascular tissues except in the bone marrow and neural tissue. The largest concentrations of lymphatic vessels can be found in the skin, respiratory system, and gastrointestinal system (Aspelund et al. 2016). The lymphatic system plays important functions in the immune system, including the absorption of gastrointestinal lipids, and in filtering fluid and larger molecules between the vascular space (blood vessels) and the extracellular space. Filtering of fluid and molecules between the vascular and extracellular spaces is known as tissue fluid homeostasis (Burggren et al. 2014).

**Lymphatic vessels** function to transport fluid, macromolecules, antigen-presenting cells, and leukocytes into the lymph nodes and then into the circulatory vessels. By filtering fluid, immune cells, and plasma proteins as they are transported from the extracellular space into the bloodstream, lymphatics help to prevent edema (abnormal fluid accumulation in the body) from developing (Martinez-Lemus and Laughlin 2015). These vessels also help to protect the body against foreign antigens and molecules by transporting immune cells. Due to their size, lymphatic vessels are necessary to assist with the absorption of dietary fat and fat-soluble vitamins that are needed by the body (Aspelund et al. 2016).

## Circulation

Due to the closure of shunts shortly after birth, the circulation of blood differs greatly between fetal and adult mammals. As an adult, unoxygenated blood from the body flows through the cranial and caudal vena cava to the right atrium of the heart. From the right atrium, it is pumped to the right ventricle and then to the lungs through the pulmonary artery. In the lungs, the blood is oxygenated and then pumped through the pulmonary veins to the cardiac left atrium followed by the left ventricle. From the left ventricle, blood is pumped through the aorta to the remainder of the systemic circulation. A small portion of blood from the left ventricle is also pumped through the coronary arteries to provide blood to the heart itself (Yin 2010).

During the mammalian fetal stage, the lungs are not fully formed and have a thick smooth muscle layer in the pulmonary arterioles. This results in an increased pulmonary arteriolar vascular resistance, which necessitates the presence of shunts to maintain proper blood flow. Initially, oxygenated blood from the placenta flows through the umbilical vein to the fetal portal vein and then to the fetal liver or through the ductus venosus. The ductus venosus is a shunt which allows blood to bypass the liver and travel directly to the caudal vena cava. From the liver, blood passes through hepatic sinusoids to the caudal

vena cava, which transports the blood to the cardiac right atrium. Once in the right atrium, a large portion of the blood is then shunted through the foramen ovale to the cardiac left atrium and then to the cardiac left ventricle. The foramen ovale is a hole in the interatrial septum that allows shunting of the blood from the right atrium to the left atrium. This blood is then pumped through the ascending aorta to the coronary arteries and brachiocephalic vessels. The remaining blood from the caudal vena cava and the blood from the cranial vena cava flows through the right ventricle to the main pulmonary artery. From here, 10% of the blood is pumped to the lungs, while the remainder of the blood is shunted through the ductus arteriosus to the descending aorta. The ductus arteriosus is a shunt that connects the main pulmonary artery and the descending aorta, by-passing the lungs (Yin 2010).

Following the fetal stage, the circulatory system undergoes a transitional phase. Immediately after birth, once respiration is initiated, the lungs receive a large amount of oxygen, which causes pulmonary arterioles to vasodilate, resulting in a decrease in pulmonary arteriolar vascular resistance. This enables blood from the right ventricle to flow into the lungs. Over time, the thick muscular layer in the pulmonary arteries will atrophy, causing a decrease in the resistance and pressure in the pulmonary artery until they reach adult levels. Also during this time, the ductus venosus and umbilical arteries will begin to close and the foramen ovale will functionally close due to changes in atrial pressures; this is then followed by anatomic closure, preventing further blood shunting. Increased arterial oxygen supply also causes the ductus arteriosus to functionally close. Finally, thrombosis and fibrosis of the ductus arteriosus results in anatomic closure (Yin 2010).

## Unique Traits

Some species have developed unique traits specific to their evolutionary requirements. For example, birds have an elevated heart rate, likely due to an elevated metabolic demand from their normal behaviors.

In fish, the heart consists of only two chambers (one atrium and one ventricle) and one pump, with blood first being pumped to the gills and then to the remainder of the systemic circulation (Stephenson et al. 2017).

Amphibians and most reptiles have a three-chambered heart with two atria and one ventricle. The ventricle in these species has an incomplete ventricular septum, or ridge, which assists in minimizing the mixing of oxygenated and deoxygenated blood. Due to this incomplete ridge, most reptiles are able to shunt their blood, if needed. The exception to this is crocodilians, which have a complete ventricular septum and therefore have developed a four-chambered heart (Kik and Mitchell 2005).

As ectotherms, reptiles have also developed an adaptation which provides them with the ability to adjust their heart rate based on environmental temperature. They are able to increase their heart rate when basking in the warm sun to increase the amount of heat their bodies absorb. When cooling, they can decrease their heart rate to minimize the amount of body heat lost (Kik and Mitchell 2005).

Marine mammals have developed unique adaptations involved in their diving response, thermoregulation, and have larger blood volumes due to their large body masses and demands on their bodies. Examples of cardiovascular adaptations needed for extended and deep diving behavior are massive heart rate reduction during diving and blood flow limitation specifically to muscles that are not as active during these behaviors. In addition, adaptive traits have arisen that allow aquatic mammals to thrive in the cooler temperatures of deep waters. For example, a counter-current heat exchange system is noted in the flukes and flippers of cetaceans (whales, dolphins, porpoises) and provides conservation of body heat (Ponganis 2009).

## Conclusion

The circulatory system is a complex system of organs and vessels that functions to transport

blood, oxygen, and other substances throughout the body and assist with thermoregulation. There are two main types of circulatory systems, closed and open, which have many differences between species. In an open circulatory system, blood is located both inside vessels and in body cavities. Blood is transported solely within vessels in a closed circulatory system. The main components of a closed circulatory system include blood, the heart, arterial vessels, capillaries, venous vessels, and the lymphatic system. Blood circulation throughout the body is a highly regulated system which differs between the fetal stage and the adult life stage. Some species also have developed unique traits specific to their evolutionary requirements.

## Cladistic Analysis

Veronique Barriel and Pascal Tassy  
Département “Origines et Evolution”, Muséum national d’Histoire naturelle, UMR 7207/CR2P CNRS-MNHN-UPMC, Paris Cedex 05, France

In systematics and evolutionary literature, cladistic analysis applies to a method of character analysis first called “phylogenetic systematics” by its inventor, the German entomologist Willi Hennig (1913–1976) in several works, from 1947 up to 1981. The words and expressions “cladistics,” “cladistic analysis,” “cladist,” and “cladogram” appeared in the year 1965 in the American literature and became popular in the 1970s. From the same origin (the Greek *clados*, branch) is the word “clade” (a branch of the tree of life). Although used by the German biologist Ernst Haeckel (1834–1919) as soon as 1866 (*kladus*), clade was not much used before the late 1950s. In other words, cladistics is the study of the branching pattern of taxa. This pattern is devoted to express the phylogenetic relationships of taxa, so that Darwin’s (1859) anticipation can be fulfilled: “Our classifications will come to be, as far as they can be so made, genealogies.”

How to hypothesize interrelationships of taxa through the study of their degree of resemblance and difference?

The answer of the cladistic analysis is to study individual characters. The method is firstly based on the conceptual dichotomy made of homology/homoplasy, that is, resemblance due to kinship/fortuitous resemblance. Secondly homology is divided into the concept of character states. Resemblance due to kinship can be the result of shared plesiomorphous (that is, primitive) states of remote common ancestry, or shared apomorphous (that is, derived, transformed) states of close ancestry. Taxa grouped by apomorphy, such as A and B of Fig. 1, are called monophyletic groups (i.e., clades). Only clades have a phylogenetic dimension: they are made of the descendants of one ancestral species. This ancestral species is a hypothesis, often called “ancestral hypothetical morphotype.” This hypothetical ancestor is made of the apomorphies reconstructed by the analysis. The phylogenetic pattern is represented by a schema called “cladogram” (Fig. 1). The cladogram displays sister group relationships, that is, closely related clades (sharing the same ancestral species). The hierarchy is this system of subordinated sister groups, and the meaning of “closely related” can be summarized in the following way: a species (or taxon) A is more closely related to another species (or taxon) B than it is to a third species (or taxon) C if, and only if, it has one ancestral species in common with B that is not also an ancestral species of C. In Fig. 1 the ancestry of A, B, and C is the branch 1, and the ancestry of A and B is branch 2 (ancestral branch) as well as node 3 (ancestral node).

As a consequence, as a node of the cladogram is one ancestral species represented by one or more apomorphies shared by the sister groups, resemblance displayed by taxa is broken into three classes: apomorphy, plesiomorphy, and homoplasy. Homoplasy may be due to the presence in several taxa of the “same” derived character state by convergent evolution (not present in the ancestry), or the apparent presence of a primitive character state may be due to a reversal (and as, a reversal, not homologous with the true primitive state). These phenomena appear in all types of characters, morphological, ethological, and

**Cladistic Analysis, Fig. 1** The structure of the cladogram. This cladogram depicts the relationships of five taxa (A, B, C, D, and E), also called terminal taxa. The taxa A and B are sister groups and form clade (A, B). The clade (A, B) and the clade (C(D, E)) are sister groups. 1 = root; 2 = internal branch; 3 = internal node; 4 = external branch. The information conveyed by 2 and 3 (apomorphies of the clade (A, B)) is the same, that is, 2 and 3 are the same. According to graph theory, branch and node such as 2 and 3 are different symbols of the same connection. According to cladistics, the list of apomorphies of either branch 2 or node 3 represents the traits of the hypothetical ancestor of (A, B) – also labeled hypothetical ancestral morphotype – as well as the diagnosis of (A, B).

molecular. The important conclusion is that global resemblance between taxa is different from relationships between these same taxa.

The notions of plesiomorphy and apomorphy are relative. The same character state is plesiomorphous at one level and apomorphous at another one. The basis of the discrimination is the concept of congruence. The superimposition of the phylogenetic pattern of each individual character displays the phylogenetic hypothesis of the taxa. Congruence identifies the different levels of the transformations: (1) the five digits of both the hand and foot seen in chimp and man are a tetrapod character, deep in the tree of vertebrates (it is an apomorphy for vertebrates but a plesiomorphy for primates) and (2) the fusion of caudal vertebrae (coccyx) is an apomorphy of hominoids (man and apes) among the primates. The levels of generality of characters have been called either “mosaic evolution” or “heterobathmy.” The first means that any given organism is made of both apomorphous and plesiomorphous characters

(mosaic). The second means that these characters indicate different levels in the branching sequence displayed by the phylogenetic tree, relatively deep (such as the five fingers, 360 million years) or relatively high (the coccyx, 16 million years). As a consequence, the species *Homo sapiens* exhibit both traits of different chronologies, a foot with five toes (a tetrapod character) and a coccyx (hominoid character).

In the history of phylogenetics, the concept of congruence appeared later to be identical to the construction of the minimal length tree in terms of evolutionary steps, that is, steps from primitive to derived transformations of each analyzed character. Both maximize the hypotheses of homology (synapomorphies), that is, minimize the number transformations and, a fortiori that of transformations not related to shared ancestry (homoplasies). The algorithms of minimal length trees developed in the late 1960s and early 1970s, especially by the American phylogeneticist Steve Farris, are based on a measured distance called Manhattan distance. This distance calculates the difference (in terms of individual character states) between taxa in relation to a common ancestry and not directly (contrary to so-called Euclidean distances). These algorithms are described as parsimony algorithms.

In the 1980s, the irresistible access to personal computers made them functional for routine work.

The peculiar behavior of molecular characters (substitutions of bases in the different genes of the genome) with intense homoplasy and identical “morphology,” that is, a stereotyped information (an adenine is an adenine), leads molecular biologists to support a weighting approach (weighted parsimony), that is, weighting the different kinds of substitutions. For instance, the information given by transversions thought to be less frequent than transitions is considered more reliable. As a consequence, transversions are given more weight. In most molecular phylogenies, as the frequency of events is considered and not only the simple presence of same nucleotides, weighting turned into model methods. When models of evolution of substitutions replace weighting, parsimony algorithms are replaced by different algorithms based on probabilities (maximum likelihood and Bayesian approaches).

## Clambering

Dionisios Youlatos  
Department of Zoology, School of Biology,  
Aristotle University of Thessaloniki,  
Thessaloniki, Macedonia, Greece

## Definition

To climb with difficulty or in a clumsy manner by using both hands and feet.

## Introduction

The word clamber is derived from the Middle English words *clamberen* and *clameren*, which are akin to the German word *klammern* denoting

the action of hooking oneself on or clinging firmly (Webster 1962). In relation to movement, it extends to a relatively awkward way of climbing, hooking, and clinging by using both hands and feet. Therefore, clambering appears to represent a mode of locomotion which incorporates the unstable, rather *maladroit*, way of negotiating rough and irregular vertical surfaces (e.g., cliffs) or navigating through unstable flexible branches in trees. Efficient clambering apparently requires cautious movements and strong holds.

### Locomotion in Treetops

In the literature related to animal, and mainly mammalian locomotion, clambering describes body displacement in multiple directions (upward, horizontal, downward) using irregular quadrupedal (i.e., four-limbed) movements across multiple, diversely oriented arboreal substrates. During these multi-directed movements, the forelimbs and hind limbs usually adopt a wide range of flexed and extended postures and may be often abducted in order to reach the diversely located available branches. Furthermore, the hooking and clinging action of clambering is assured by the grasping forefeet and hind feet that establish firm grips on the branches.

During clambering, the posture of the body may be also variable and is important for determining the ways that both forelimbs and hind limbs are used. Thus, pronograde clamber (or scramble) defines a nonsuspensory quadrupedal progression lacking a regular gait and keeping the body pronograde (i.e., horizontal) (Hunt et al. 1996). In this case, the arboreal substrates are usually small in diameter, rather flexible, bending under the animal's weight, irregularly placed, and variously angled. It usually occurs among the terminal branches of tree crowns and body progression is horizontal to slightly angled, and speed may be slow to medium-fast. This locomotor mode is often used by arboreal mammals, but behavioral percentages of use can be variable, depending on their anatomy and size. Smaller arboreal mammals tend to use clambering less frequently than larger ones, and more arboreally

committed mammals (e.g., primates) use it more often than more terrestrially adapted species.

On the other hand, orthograde clambering is an essentially horizontal or slightly angled progression keeping the body orthograde (i.e., vertical) in a forelimb-suspensory manner, but with the hind limbs assisting (Hunt et al. 1996). In this case, all four limbs move the body forward, with most body weight borne by the abducted forelimbs. However, the role of the hind limbs is to provide support from virtually any limb posture, including completely abducted. This locomotor mode can be also slow to moderately fast and usually occurs on intertwined small and flexible branches. In contrast to pronograde clambering, orthograde clambering is not very common and is usually adopted by some suspensory primates. For instance, the prehensile-tailed howler, spider, and woolly monkeys of South America moderately use this mode among small and medium branches of tree crowns (Cant et al. 2001; Youlatos 2008). In contrast, this way of locomotion appears to be more common in orangutans among apes, especially when traveling on small unstable branches within and across tree peripheries in the canopy (Cant 1987; Thorpe and Crompton 2006).

### Clambering and Cognition

Behavioral observations of free-ranging monkeys and apes have well established that pronograde and basically orthograde clambering are strongly related to locomotion upon small, fragile, flexible intertwined branches in tree crown peripheries. This fragile and unstable habitat, as a consequence of large body size, apparently represents an ever-changing and unpredictable environment that requires good knowledge and planning for competent and efficient navigation. In effect, mistakes may lead to falls from the canopy, which can be ultimately lethal. Therefore, apart from morphological adaptations that enable safe anchoring of the hands and feet, this endeavor also represents a mental challenge as it requires the failure of stereotyped behavioral responses (which suit better in more stable environments) and stimulation of

continuous experimentation (trial and error, in a relatively safer way). In this way, clambering has been supposedly reinforced by cognizance of one's actions, the ability to engage in a type of mental experimentation or simulation in which one is able to plan actions and predict their likely consequences before acting that subsequently led to the emergence of a limited self-concept (Povinelli and Cant 1995). However, data on the locomotion and postures of other great apes (gorillas, chimpanzees, bonobos) in relation to their cognitive capacities and self-concept fail to support such a strong causal interrelation: many apes depict increased intelligence and self-concept but do not seem to use high rates of clambering locomotion (Hunt 2004). Beyond that, the link between foraging for arboreal sources and development of great ape intelligence, which can be linked to clambering locomotion, as the major means for negotiating their access and acquisition, also appears not to be a strong one (Russon 1998). Large body size, complexity of social interactions, food source distribution in space and time, and food chemistry, examined within a phylogenetic context, may surely come into play, when considering the evolution of intelligence among great apes and humans (Hunt 2004).

## Clark L. Hull

Gonzalo Miguez, Mario A. Laborda and  
Vanetza E. Quezada-Scholz  
Departamento de Psicología, Facultad de Ciencias  
Sociales, Universidad de Chile, Santiago, Chile

Due to his rigorous and ingenious method, diligent studies, and the impact of his work, Clark Hull (1884–1952) is considered one of the most prominent researchers in psychology. He was born in a log house near Akron, New York, USA, and 3 years later, he and his family moved to Michigan to set a farm. Initially interested in engineering, Hull's decision of pursuing a career in experimental psychology occurred around 1908, during his recovery from a polio attack. At that time, he was influenced by Williams James's *Principles of Psychology* and his own search for an

intellectually growing field, one in which he could use his aptitudes in technology and his interest in building automatic apparatus (Hull 1952a) among them, one that could simulate the main characteristics of the conditioned reflex described by Pavlov. Hull obtained his B.A. at the University of Michigan, in 1913, and his Ph.D. at the University of Wisconsin in Madison, in 1918. There, he was motivated and influenced by Pavlov's book, *Conditioned Reflexes*. His dissertation, entitled *Quantitative aspects of the evolution of concepts*, was later published in *Psychological Monograph* (Hull 1920). His teaching career started early as a school teacher, before he obtained his B.A., after which he was offered a position as Instructor at the University of Wisconsin 2 years before he graduated. In 1929, he was invited to work as a Research Scientist at Yale University, due to his interest in applications and his abilities in statistics and quantitative modeling.

As experimental psychologist, Hull was attracted to a broad range of topics. Although his interest in learning was evident since his doctoral research, he also dedicated time to study aptitude testing and hypnosis, fields in which he published influential manuscripts and books. Nevertheless, a few years after he arrived at Yale, he dropped other areas of research and focused mainly on learning and motivation. Hull became one of the most cited psychologist in the 1940s in the learning and motivation literature. The formulation of his ideas into systems of principles that rule behavior included definitions, postulates, theorems, quantitative formalization of ideas, and the empirical evidence to support it. He developed his ideas in several papers (e.g., Hull 1930, 1937) and three books: *Principles of Behavior* (Hull 1943), *Essentials of Behavior* (Hull 1951), and *A Behavior System* (Hull 1952b).

Essentially, Hull's theory of learning assumes that a reinforcer works through the reduction of a drive (Postulate 3, Hull 1952b), and that the memory trace that links a stimulus and a response (i.e., habit strength) is directly related to the number of reinforced trials (Postulate 4, Hull 1952b). Then, the potential to produce a response (i.e., excitatory potential) results from the product of habit

strength and drive. These three variables (drive, habit strength, and excitatory potential) are considered intervening variables. These variables explain the observed relationship between inputs, or independent variables (e.g., number of reinforcement and hours of deprivation) and outputs, or dependent measure (e.g., latency to response). Hull proposed a definition and formalization of these variables and relationships. As more variables and interactions between variables needed to be accounted for, the system grew in assumptions to allow their codetermination. In its final version, Hull's proposed system had 17 postulates that contained a total of 178 propositions. Hull collected evidence for 121 of them and concluded that 106 were valid, 14 probably invalid, and 1 definitively invalid.

He considered the abstract reasoning processes of the organism as a mechanical process which could be explained from the laws of matter and movement. That is why in his learning theory, he tried to connect two empirical aspects of behavior (independent and dependent variable) through different theoretical concepts (intervention variables) that should have a physiological substratum.

Hull received great recognition and influence among psychologist. He was recognized with the Warren Medal of the Society of Experimental Psychology in 1945 and served as the President of the American Psychological Association in 1936. His students were strongly influential in several colleges and universities, and they continued to disseminate and complement Hull's work even after his death. Psychologist, such as Kenneth Spence, Neal Miller, and O.H. Mowrer, were among Hull's students, helping him to develop his theory, spread the use of the hypothetical-deductive model, and were very influential on their own, in the fields of learning, motivation, cognition, and behavior in humans and animals.

## Introduction

Classical or Pavlovian conditioning is a type of learning where two or more events of the environment are associated. This type of learning helps

organisms to organize their behavior and represent their world. In a classic experiment, Pavlov (1927) discovered that a dog would salivate to the presence of a sound if this sound was previously presented contiguously with food powder. Pavlov called the food powder an unconditioned stimuli (US) that evoked a response by its own, which he called an unconditioned response (UR). The sound was originally a neutral stimulus that did not produce any relevant response, but after being presented with the food, the sound became a conditioned stimulus (CS), which elicited a conditioned response (CR). To Pavlov, this response was “conditional” to the unconditioned stimulus, thereby the name. The study of classical conditioning has changed since Pavlov’s years; we now know that classical conditioning is involved in much more than only simple reflexes and that it is a complex process involving complex responses. However, the basic concepts presented by Pavlov have remained in the vocabulary of researchers and the psychologists interested on associative learning.

A CS is a stimulus that, after training, predicts that the US will occur, usually causing an anticipatory CR. The US, by contrast, is a stimulus that does not need training to elicit a response and is usually relevant to the organism (Pavlov 1927). CSs and USs are often called by other names which allude to the same concepts. The CS is also referred sometimes as a cue or a predictor. The US is often referred as the outcome or the consequence. All these names are used somewhat indistinctively from another.

Classical conditioning is crucial for animals to be prepared for or anticipate events of the environment, and to predict what will happen around them. Consequently, it plays an important role for animals to adapt to their environment (Domjan 2005). The next sections will review how the view of classical conditioning has changed from its discovery, the basic preparation and phenomena of classical conditioning studied in the laboratory, and some of the most influential theoretical developments in the area. We will also cover how classical conditioning helps individuals to adapt to their environments, some of its main applications in therapeutic contexts, and its current state as theory and tool in Psychology.

## Historical Background

Pavlovian or classical conditioning was discovered independently in Russia and in the USA, at the end of the nineteenth century. Edward Twitmyer, at the University of Pennsylvania, investigated whether the patellar tendon or “knee-jerk” reflex worked under facilitating conditions. The sound of a bell signaled with 500 ms of anticipation the knee tapping. Shortly afterwards, Twitmyer observed that participants extended their knees immediately after the sound of the bell but in absence of any tap to the knee. Once it was demonstrated that participants were not doing it intentionally, Twitmyer concluded that some stimulus other than the usual one had elicited the reflex.

Twitmyer presented his findings at the Annual Meeting of the American Psychological Association with little impact, and he did not extend his work on conditioning. Thus, its discovery is credited to Ivan Pavlov, the Russian physiologist who worked approximately at the same time on conditioning in his laboratory, and upon realizing what he had found, dedicated the following decades of his life to the study of classical conditioning.

Pavlov’s work with conditioned responses became widely known during the first decades of the twentieth century, particularly in the USA. For instance, as early as 1914 John B. Watson and his student Karl Lashley were conducting studies in classical conditioning at Watson’s laboratory. Watson advocated in favor of the conditioned reflex as an explicative mechanism for many psychological processes and was heavily influential in its adoption by American psychologists. The publication of *Conditioned Reflexes* in 1927 (translated by G. V. Anrep, former student of Pavlov) further helped increase the interest in classical conditioning.

During the first half of the twentieth century, classical conditioning was widely studied as one of the fundamental learning processes (the other one being instrumental or operant conditioning). Basic experimental paradigms were extended from the original Pavlovian design and included preparations still in use today, such as fear

conditioning (for a detailed depiction of experimental preparations, see the corresponding section), also extended to different species including rabbits, rats, and humans. Early learning models also were developed during this time, for instance, Clark Hull’s *Principles of Behavior* (1943) and Edward Tolman’s influential *Purposive Behavior in Animals and Men* (1951). Theoretical models during this period followed closely the original Pavlovian view of classical conditioning. Primarily, the predominant conception was that conditioning was an automatic, low-level process which involved mostly smooth muscle tissue and glandular responses such as those studied by Pavlov, and that the key factor that determined how two stimuli are associated was temporal contiguity. This view shifted dramatically during the second half of the twentieth century as the result of new evidence (e.g., blocking effect; Kamin 1969), which suggested to learning theorists that classical conditioning was a more complex and rich learning process. For example, Rescorla (1988) summarized classical conditioning as “the learning that results from exposure to relations among events in the environment. . . a primary means by which the organism represents the structure of its world” (p. 152).

In parallel with this theoretical and empirical developments, there was also an important development of clinical applications based on associative principles. For example, the work of John B. Watson, Rosalie Rayner, and Mary Cover Jones showed how classical conditioning was able to explain the acquisition of fear as well as evaluate techniques to treat it. Later the South-African psychiatrist Joseph Wolpe developed the systematic desensitization procedure to treat anxiety, applying what was learned in the experimental laboratory to real life situations. These instances laid the ground for an empirical approach to psychotherapy in general and particularly for behavior therapy. The translation from basic experimental research to clinical application still continues today, with a growing corpus of empirical results in many areas.

As a result of the empirical and theoretical shift mentioned above, research in classical conditioning has growth beyond its origins and has

included novel experimental paradigms which came to be seen as associative in nature (e.g., contingency judgment and causal learning; Dickinson and Shanks 1985). An important development also occurred in models of associative learning (e.g., Mackintosh 1975; Rescorla and Wagner 1972). The mathematical formalization of learning models provided testable predictions which further helped bolster research in classical conditioning, in a trend that continues today. This expansion in the study of classical conditioning was also notorious in what is called the “functional analysis” in contemporary research (e.g., Domjan 2005; Hollis 1997), an approach that focused on investigating the role and properties of classical conditioning as an evolutionary adaptive process.

Currently, classical conditioning is an active research field, with relevant and growing links with the contemporary neuroscience and cognitive psychology, and particularly relevant as a model of information processing (for more details, see the final section of this entry).

## Major Concepts

This section will review some relevant basic aspects of Classical conditioning, such as Pavlovian acquisition, excitation, extinction and inhibition, and relevant factors such as contiguity and contingency.

The process by which the CR comes under control of the CS is called acquisition. This control is usually acquired by the CS after being paired with the US. The CS is generally a stimulus that by itself and prior to any training does not elicit the target response. Such target response is typically similar to that elicited by the US. Because of this, the CS is usually viewed as more neutral than the US, and this relative difference is used to define what the CS and the US are in any given experiment. For example, a weak electric shock can be used as US in an experiment, and as CS in a second one, provided that the corresponding CS and US are weaker and more intense, respectively. After one or more pairings (the specific number will vary depending on the

experimental preparation), subjects will respond to the CS in a similar way to how they respond to the US, or, depending on the task, with a response related to the specific features of the CS.

Several parameters affect the acquisition of a CR and thus will vary across experimental preparations. First, more intense or salient stimuli are generally associated with faster and stronger acquisition (Pavlov 1927). Acquisition also proceeds faster when the stimuli are novel, as shown by the “pre-exposure” or “latent inhibition” effect (Lubow and Moore 1959). Finally, acquisition is also affected by the temporal relationship between the CS and the US (inter-stimuli interval) and between each trial (inter-trial interval; e.g., Gallistel and Gibbon 2000).

Contiguity and contingency are two key concepts in Classical conditioning. Contiguity refers to the spatial and/or temporal relationship between the CS and the US. Contingency is the relationship of probability between the CS and the US, that is, how likely it is that both stimuli are presented together compared to the likelihood of them presented alone.

Variations in contiguity have an impact on the effectiveness of conditioning, and thus have been extensively investigated. The most used procedure is the so-called delay conditioning, in which the US begins after the onset of the CS but overlaps with it. This delay between the onsets of both stimuli can be short or long. In “trace” conditioning, there is a time gap between the offset of the CS and the onset of the US. The association in this case is supposed to occur between a trace of the already absent CS and the US, hence the name. Both stimuli can also be presented simultaneously. Finally, in backward conditioning, the usual temporal relationship is inverted, and the US is presented before the CS.

Contiguity has had theoretical value as an explanation of Classical conditioning. For instance, for Pavlov (1927), contiguity was the most important element for an association to occur. Past and current views about the role of contiguity in conditioning are discussed in detail in the corresponding section.

Contingency, on the other hand, is classified in three variations depending on the relative

probability of the CS and the US. Contingency can take positive, negative, and zero values. In positive contingency, the US is more likely to occur when the CS is presented than when it is not; in negative contingency, the US is less likely to occur when the CS is presented than when it is not; and in zero contingency, the probability of the US is the equivalent in the presence of the CS and in its absence.

The idea of contingency has been relevant for modern conceptualizations of Classical conditioning. Following the work of Rescorla (1969), contingency is thought to reflect the informational value of the CS, that is, whether the CS gives any meaningful information about the occurrence of the US. Thus, in positive contingency, the CS is a reliable predictor of the US, while in negative contingency, the CS is a predictor of the absence of the US, and in zero contingency, the CS does not give any information about the occurrence of the US. Different models give alternative interpretations for each case, and thus the role of contingency for models of Classical conditioning is further developed in the corresponding section.

The variations in the informational value of the CS regarding the US are closely related to the concepts of excitation and inhibition. Excitatory conditioning refers to when the CS is a good predictor of the US as in positive contingency. Conditioned inhibition, on the other hand, refers to when the CS is a predictor of the absence of the US, as in negative contingency.

A key feature of conditioned inhibition is that it occurs when there is a previous expectancy of the US. In other words, the organism must somehow expect the occurrence of the US so that the inhibitory CS can predict its absence, that is, there must be at least a previous excitatory context. The procedures designed to train conditioned inhibition all include a previous expectancy of the occurrence of the US. In the Pavlovian or standard conditioned inhibition procedure (Pavlov 1927), in an initial phase subjects receive CS1-US trials for the CS1 to provide an excitatory context. In a second phase, CS1 is presented together with a CS2 without the US. With this procedure, CS2 should become inhibitory, since it signals the absence of the US. In the negative contingency

procedure (Rescorla 1969), the CS is negatively correlated with the US. In this case, the excitatory expectancy is supposed to be given by the experimental context. Because the US is presented consistently in the presence of signals provided by the experimental context, it should become excitatory while the CS becomes inhibitory.

Conditioned inhibition is supposed to be contrary to excitation in that while the latter increases CRs, inhibition does not, which makes measuring it more difficult. Several techniques have been developed to overcome this problem:

- (a) Bidirectional responses: Some responses can increase or decrease compared to a baseline. Typical examples are the approach/avoidance system, or physiological responses such as the heart rate. A bidirectional response may, for example, decrease in presence of an inhibitor and increase in the presence of an exciter. Nevertheless, some responses have a very low baseline, making this type of measurement not ideal.
- (b) Summation/Retardation tests (Rescorla 1969): The summation test consists of the presentation in compound of an excitatory CS+ and an inhibitory CS-. If the CS- is effectively a conditioned inhibitor, it should decrease the response elicited by the CS+, compared to presentations of the CS+ alone. In the retardation test, the CS- is paired with the US. If the CS- did acquire conditioned inhibition, this reacquisition training should proceed slower compared to a novel CS.

After acquisition, repeated presentations of the CS alone cause a gradual decrement in the conditioned responding, which can eventually lead to its complete suppression. Both the procedure and its result are called extinction. Pavlovian extinction has been widely researched in the last decades for the study of its mechanisms and clinical applications (mainly for exposure therapy, details, see the “[Applications Outside of the Laboratory](#)” section).

One relevant feature of extinction is that its effect on behavior is usually not permanent, and the response to the CS recovers under several circumstances. Renewal is the recovery after the

subject is moved to a different context to the one in which extinction was conducted (e.g., Bouton and Bolles 1979). There are three types of renewal, depending on the procedure. ABA Renewal occurs when acquisition is conducted in a Context A, extinction in a Context B, and the subject is then tested in the acquisition context. ABC Renewal is similar, although test is conducted in a different Context C. Finally, in AAB Renewal both acquisition and extinction are conducted in Context A while testing is conducted in a different context. Spontaneous recovery is the response recovery that happens when a time interval is introduced between extinction and testing (Pavlov 1927). In reinstatement (Rescorla and Heth 1975), the response recovers when the US is presented again after extinction. Finally, when subjects receive again CS-US pairings after extinction, response recovers faster compared to the acquisition of a newly trained association (rapid reacquisition; Pavlov 1927).

## Experimental Preparations

This section will focus on experimental preparations used in Pavlovian research such as fear conditioning, taste aversion, and others. One important issue about Classical conditioning is the question regarding the generality of Pavlovian phenomena. Pavlov himself (e.g., Pavlov 1927) studied conditioning using stimuli of different modalities (i.e., visual cues, tones, tactile stimuli) to examine whether conditioning occurred or was similarly effective in all cases. The following years saw the development of many different experimental preparations, using CSs and USs of different modalities, and different ways to measure the conditioned response.

**Fear conditioning:** Fear conditioning is one of the most studied experimental preparations in Classical conditioning. It consists of the pairing of a given CS with an aversive or fear-eliciting US. After training, the CS comes to elicit responses (i.e., anxiety and/or avoidance) originally elicited by the aversive US, which can be used to measure the amount of learning about the now aversive CS.

In most of the studies, both with human participants and non-human subjects, fear conditioning is examined with the pairing of a CS or context and a mild electric shock. The shock is regulated in its intensity by the participants themselves in the case of humans, to be aversive without being physically harming. Fear is indirectly measured by several physiological and behavioral responses. In the case of human participants, these measures include skin conductance or galvanic skin response, pupillary dilation, and, particularly in the case of exposure therapy, approach/avoidance responses. In rats, freezing is usually reported as a measure of fear. Freezing can be measured as the time the rat stays without moving, which can be recorded and then examined by independent judges or by how much it disrupts the rat's normal behavior. Similar is the procedure of conditioned emotional response or "conditioned suppression." In this procedure, the rat is initially trained to press a lever for food. In a second phase, the subject receives CS-shock pairings. During testing the rat has access again to the lever, and lever press is measured in presence of the CS and in its absence. Fear is indicated by the decrement in lever pressing in the presence of the fear-eliciting CS compared to the baseline responding without the CS. There are several variations in which the effect of fear is measured against different behaviors such as licking water tubes or magazine entries for pellets, although the basic principle is the same.

A suppression ratio can be calculated as an index for the suppression of behavior. The suppression ratio considers how much responses occurred during the CS relative to the sum of those responses and the baseline responses registered before the onset of the CS. The suppression ratio ranges between 0 and 0.5, where 0 indicates no response and thus complete disruption of behavior (i.e., fear) and 0.5 indicates no fear.

**Conditioned taste aversion:** Classical conditioning plays a relevant role in the acquisition of taste preferences and aversions (Garcia and Koelling 1966). In a conditioned taste aversion experiment, subjects (typically rats) receive a flavor-CS (i.e., food or liquid) followed by sickness provoked by administering lithium chloride

or other emetic procedure. Conditioned taste aversion can be acquired after a single CS-US pairing, which is typical in aversive conditioning, but not observed in appetitive paradigms. Also, subjects may present taste aversion even if hours have passed between the presentation of the flavor-CS and the internal sickness. These features have been of theoretical relevance for discussing the role of preparedness or pertinence of the stimuli in Pavlovian learning.

**Eye-blink conditioning:** The eye blink is a reflex common to a wide variety of species. Any object approaching the eye, such as an airpuff, will elicit the reflex response. Eye-blink conditioning thus works by pairing a visual or auditory cue with a reflex-eliciting stimulus, usually an air puff or a mild electric shock (Gormezano 1966). Eye-blink conditioning has been extensively researched because of its simplicity in humans and other animals. It has also been relevant for understanding basic neural mechanisms of learning and memory.

**Sign and goal tracking:** Sign- and goal-tracking are terms that refer to similar tasks and include related preparations as autoshaping (Brown and Jenkins 1968). In sign-tracking, a visual CS is paired with an appetitive US, such that after repeated pairings, the animal responds by approaching and contacting the CS. In a typical experiment, a pigeon is trained to associate a keylight (i.e., an illuminated disc) with the delivery of grain. After some trials, the pigeon will approach the keylight instead of the food magazine and peck it as if it was a pellet of grain. In goal-tracking, the basic procedure is similar although the measured response is the approach to the place of appearance of the US.

Since both tasks are similar, some research has examined the factors that may explain whether organisms will respond with either sign- or goal-tracking. For instance, it has been shown that rats tend to show more goal- than sign-tracking, that is, rats approach the food magazine instead of the CS, while pigeons show the opposite pattern. It has also been suggested that the observed behavior depends on the contiguity between the CS and the US: goal-tracking would be more likely when the CS and the US are separated temporally and

spatially, while sign-tracking would be more probable when both stimuli are close.

Sign-tracking, and particularly autoshaping, has been historically a relevant phenomenon for classical conditioning. From the early conceptualizations of Pavlov, it was considered that classical conditioning affected reflexes and glandular responses, while responses involving skeletal muscles were the domain of operant conditioning. Sign-tracking, as primary classical conditioning procedure that involves complex skeletal responses, showed that this distinction was not empirically valid (Hollis 1997).

**Drug tolerance:** Drug tolerance is the decrement in the effect of a drug after its repeated administration or, conversely, the need of higher doses to obtain the same original effect. Drug tolerance has a learning component in what is called “associative tolerance.” Research has shown that each episode of drug administration is a conditioning trial, in which the effect of the drug is associated with, and thus predicted by, a wide arrange of stimuli (Siegel et al. 2000). For instance, the presence of friends or bottles can act as a signal for the consumption of alcohol. Within this framework, tolerance is the product of anticipatory conditioned responses to these signals that predict the drug and thus allow the organism to adapt to its effect. For example, a well-known effect of alcohol is the decrement in body temperature. The compensatory reaction by the organism is to rise the temperature to counteract the effect of alcohol intake. This response is specific to the cues or contexts associated with the drug, that is, associative tolerance will be evidenced only in the specific circumstances linked to usual drug consumption where the drug-predictive cues are present.

**Causal learning:** Causal learning is a broad term that encompasses different methods by which people learn about the causal structure of a given task. One of them is the so-called human contingency learning, although the terms “predictive learning” and “causal judgment” are also used in the literature. Participants, in a contingency learning task, are presented with sets of stimuli and then asked to assess the causal relationship between them. For example, in what is perhaps the most used causal learning task, participants assess

the causal relationship between meals or chemicals and sickness in a hypothetical patient. In such tasks there are many ways of assessing this relationship, from simply giving a prediction in an arbitrary scale to more behavioral or physiological measures like response latency and eye tracking. Contingency learning shows many of the phenomena found in classical conditioning, which is why it is usually explained in terms of associative learning models (Dickinson and Shanks 1985). For instance, acquisition and extinction of a causal relationship proceed in a similar manner to other Pavlovian preparations, as do cue competition effects.

**Conditioned Analgesia:** Stressful situations can produce an unconditioned reduction in the severity of pain. Consequently, an initially neutral stimulus, through pairings with a stressor, also comes to produce a reduction in the response to painful stimulation. Such reduction is often called conditioned analgesia (i.e., conditioned stress-induced analgesia). This preparation has been used both with human and non-human animals, who typically report or show behavior indicative of lower pain when the associated CSs are presented (see Miguez et al. 2014, for a review).

## Key Phenomena

Several learning phenomena have been historically relevant for the study of Classical conditioning and for the development of theoretical models. This section describes some of them, such as cue competition and interference phenomena.

**Cue Competition:** Cue or stimulus competition refers to a set of Pavlovian phenomena, in which multiple CSs are trained simultaneously with an outcome or US. In these cases, all CSs involved appear to “compete” with each other for the conditioned response, thus the name. When both stimuli are tested individually, one will elicit less-conditioned response than the other one.

**Overshadowing** is a cue competition effect first identified by Pavlov (1927). In overshadowing, two CSs are presented simultaneously followed by the US. The critical feature is that one of the CSs is defined as more salient than the other (i.e.,

more intense or relevant). When both stimuli are tested, subjects show more conditioned response in the presence of the more salient CS compared to the less salient one.

**Potentiation** (Rusiniak et al. 1979) is a variation of the overshadowing procedure frequently observed in taste aversion experiments. The procedure is similar to overshadowing training, but the result is the opposite, that is, the less salient CS elicits more conditioned response than the more salient CS during testing. Some factors have been suggested to facilitate potentiation over overshadowing: the trace between CS and US, the specific experimental preparation (most of the observations of potentiation have been conducted in taste aversion), and the relative salience of the trained CSs.

**Blocking** is perhaps the most investigated cue competition effect. In blocking (Kamin 1969), subjects receive an initial phase of CS1-US until the conditioned response to CS1 is reliably established. In a subsequent phase, subjects are trained with CS1-CS2-US pairings, where CS2 is a second, different CS. When both CSs are tested individually, subjects respond more to CS1 than to CS2, that is, CS2 is “blocked” by the CS1.

**Interference:** In Classical conditioning, it is frequently observed that two different independent trainings that share a common element can affect how subjects respond to the stimuli involved in each training. This general phenomenon is called “interference” (Bouton 1993).

Pavlovian interference can be examined in two different ways. In proactive interference, a first-learned association can affect responding to a second-learned association; in retroactive interference, a first-learned association can be affected by a second-learned association.

Furthermore, interference also varies depending on the common element shared by the different associations; cue-interference refers to the training in which the first- and the second-learned association share a common US but different CSs. For example, subjects trained with tone CS-shock pairings in a first phase, and light CS-sock pairings in a second phase will show less fear to the light compared to subjects that received only one of either phase of training.

Outcome-interference refers to different associations sharing the same CS but different USs or the absence of a US as in extinction. For example, in the case of counterconditioning, a tone CS can be initially paired with a shock, and in a second phase with food pellet. Another example is latent inhibition, in which subjects are presented to a CS alone (without a US or consequence) during a first phase, and then to CS-US pairings during a second phase. Such subjects acquired excitatory conditioning slower relative to subjects that did not experienced the first phase.

## Theoretical Developments

Researchers and theorists of learning have created several accounts to explain how stimuli are associated and what happens when we observe blocking, inhibition, or any other conditioning phenomena. These accounts are usually referred as theories or models of conditioning or learning.

The first theory of conditioning is as old as conditioning itself. Pavlov (1927) thought that during the presentation of the US, a node in the brain was activated, which was linked to a response node for the unconditioned response. When the CS started to be paired with the US, the CS-node began to supplant the US-node, thereby producing the same response that the US produced before. This early theory is not able to explain all the phenomena and contemporary evidence on conditioning but serves as a first explanation of how animals learn new conditioned reflexes linked to innate responses.

Most of the current models of learning are influenced by proposals from Clark C. Hull, his disciple Kenneth Spence, and Bush and Mosteller. In different ways, they all suggested that learning is a function of a maximum amount of possible learning, and what or how much the subject has learned at that moment. This rule assumes that learning is a gradual process based on error correction, that is, that the amount of learning gained each time that the stimuli are paired (the rate of change on learning) would be progressively smaller as learning progresses.
